#### Abstract

We consider the problem of 20 questions with noisy answers, in which we seek to find a target by repeatedly choosing a set, asking an oracle whether the target lies in this set, and obtaining an answer corrupted by noise. Starting with a prior distribution on the target's location, we seek to minimize the expected entropy of the posterior distribution. We formulate this problem as a dynamic program and show that any policy optimizing the one-step expected reduction in entropy is also optimal over the full horizon. Two such Bayes-optimal policies are presented: one generalizes the probabilistic bisection policy due to Horstein and the other asks a deterministic set of questions. We study the structural properties of the latter, and illustrate its use in a computer vision application. Keywords: twenty questions; dynamic programing; bisection; search; object detection; entropy loss; sequential experimental design; Bayesian experimental design

## 1. Introduction

In this article, we consider the problem of finding a target $X^{*} \in \mathbb{R}^{d}$ by asking a knowledgeable oracle questions. Each question consists in choosing a set $A \subseteq \mathbb{R}^{d}$, querying the oracle whether $X^{*}$ lies in this set, and observing the associated response. While this is closely related to the popular game of "twenty questions", we consider here the case where answers from the oracle are corrupted with noise from a known model. This game appears naturally in a number of problems in stochastic search, stochastic optimization, and stochastic root finding. In this paper we present an illustrative application in computer vision.

We consider a Bayesian formulation of this problem using entropy loss. In $d=1$ dimension, we seek to minimize the expected entropy of the posterior after a fixed number of questions. After formulating the problem in Sec. 2, we show in Sec. 3 that any policy myopically maximizing the expected one-step reduction in entropy is also optimal in a fully sequential sense (Theorems 1 and 2), and to follow such a policy it is sufficient to query sets $A$ whose posterior probability of containing $X^{*}$ is a specific

[^0]value given in Theorem 2. We then provide two specific Bayes optimal policies. The first, described in Sec. 4.1, poses questions about intervals, $A=(-\infty, x)$. The second, which we call the dyadic policy and describe in Sec. 4.2, poses questions about more general sets. We also provide further analysis of this second policy: a law of large numbers and a central limit theorem for the posterior entropy (Theorem 3); and an explicit characterization of the expected number of size-limited noise-free questions required to find the target after noisy questioning ceases (Theorem 4). Sec. 5 considers a modified version of the entropic loss in $d=2$ dimensions, and shows that a simple modification of the dyadic policy is asymptotically Bayes optimal for this loss function (Theorem 5). Sec. 5 also provides a central limit theorem for the posterior entropy under this policy (Theorem 6). Sec. 6 provides an illustrative application in computer vision, and Sec. 7 concludes the paper.

When the noise corrupting the oracle's responses is of a special form, that of a symmetric channel, the Bayes optimal policy for $d=1$ with questions $A$ restricted to be intervals (described in Sec. 4.1) takes a particularly natural form: choose $A=(-\infty, x)$ where $x$ is the median of the posterior distribution. This policy, called the probabilistic bisection strategy, was first proposed in [12] (republished in [13]). This policy was recently shown to be optimal in the binary symmetric case by one of the authors in [31]. [4] introduces a similar procedure that measures on either side of the median of the posterior over a discrete set of points, and shows that its error probability decays at an asymptotically optimal rate. For a review of these two procedures, see [5]. [14, 1] also both consider a noisy binary search problem with constant error probability over a discrete set of points, and give optimality results for policies similar to measuring at the median of the posterior. In [14], this is part of a larger analysis in which the error probability may vary. [19, 20] analyze noise-tolerant versions of generalized binary search for searching in a space of hypotheses. A parallel line of research has considered the case when the oracle is adversarial rather than stochastic, and is surveyed in [21].

When the questions are restricted to be intervals, the problem that we consider is similar to the stochastic root-finding problem considered by the seminal paper [24] and generalized to multiple dimensions by [3]. In the stochastic root-finding problem, one chooses a sequence of points $x_{1}, x_{2}, \ldots$ to query, and observes the corresponding values $f\left(x_{1}\right), f\left(x_{2}\right), \ldots$ of some decreasing function $f$ at $x$, obscured by noise. The goal in this problem is to find the root of $f$. Procedures include the stochastic approximation methods of [24, 3], as well as Polyak-Ruppert averaging introduced independently by [25, 22]. Asymptotic rates of convergence of these procedures are well understood see [15]. Our problem and the stochastic root-finding problem are similar because, if $X^{*}$ is the root of $f$, then querying whether $X^{*}$ is in $(-\infty, x)$ can be recast as querying whether $f(x)<0$. The problems differ because the noise in observing whether $f(x)<0$ depends upon $x$ and is generally larger when $f(x)$ is closer to 0 , while in our formulation we assume that the distribution of the oracle's response depends only on whether $X^{*}$ is in the queried subset or not.

Both our problem and stochastic root-finding lie within the larger class of problems in sequential experimental design, in which we choose at each point in time which experiment to perform in order to optimize some overall value of the information obtained. The study of this area began with [23], who introduced the multi-armed bandit problem later studied by $[16,2,11,32,33]$ and others. For a self-contained discussion of sequential experimental design in a Bayesian context, see [7].

## 2. Formulation of the problem

Nature chooses a continuous random variable $X^{*}$ with density $p_{0}$ with respect to the Lebesgue measure over $\mathbb{R}^{d}$. The fact that $X^{*}$ is continuous will turn out to be important and the arguments presented below do not generalize easily to the case where $X^{*}$ is a discrete random variable.

To discover $X^{*}$, we can sequentially ask $N$ questions. Asking the $n^{t h}$ question, $0 \leq n \leq N-1$, involves choosing a Lebesgue measurable set $A_{n} \subset \mathbb{R}^{d}$ and evaluating: "Is $X^{*} \in A_{n}$ ?". To avoid technical issues below, we require that $A_{n}$ is the union of at most $J_{n}$ half-open intervals, where $J_{0}, J_{1}, \ldots$ is a fixed sequence of natural numbers. The answer, denoted $Z_{n}$, is the indicator function of the event $\left\{X^{*} \in\right.$ $\left.A_{n}\right\}$. However, $Z_{n}$ is not openly communicated to us. Instead, $Z_{n}$ is the input of a memoryless noisy transmission channel from which we observe the output $Y_{n+1}$. $Y_{n+1}$ is a random variable which can be discrete or continuous, univariate or multivariate. The memoryless property of the channel expresses the fact that $Y_{n+1}$ depends on $Z_{n}$, but not on previous questions or answers. As a consequence, repeatedly answering the same question may not provide the same answer each time. Moreover, we assume that the distribution of $Y_{n+1}$ given $Z_{n}$ does not depend on $n$. There is a measure $\mu$ on the space in which $Y_{n+1}$ takes value, and the density with respect to $\mu$ of $Y_{n+1}$ given $Z_{n}$ is

$$
\frac{P\left(Y_{n+1} \in d y \mid Z_{n}=z\right)}{d \mu}= \begin{cases}f_{1}(y) & \text { if } z=1  \tag{1}\\ f_{0}(y) & \text { if } z=0\end{cases}
$$

If $Y_{n+1}$ is discrete, then we make take $\mu$ to be a discrete measure, while if $Y_{n+1}$ is continuous we may take $\mu$ to be the Lebesgue measure. We require that the Shannon entropy of the conditional distribution $P\left(Y_{n+1} \in \cdot \mid Z_{n}=z\right)$ be finite for both $z=0$ and $z=1$. At any time step $n$, we may characterize what we know about $X^{*}$ by computing the conditional density $p_{n}$ of $X^{*}$ given the history of previous measurements $D_{n}=\left(A_{m}, Y_{m+1}\right)_{m=0}^{n-1}$. Following the terminology of Bayesian statistics, we call $p_{n}$ the posterior density. The study of the stochastic sequences of densities $p_{n}$, under different policies, constitutes the main mathematical contribution of this paper. For an event $A$, we will use the notation

$$
p_{n}(A)=\int_{A} p_{n}(x) d x
$$

The posterior density $p_{n+1}$ of $X^{*}$ after observing $D_{n+1}$ is elegantly described as a function of $p_{n}, f_{0}, f_{1}$, the $n^{\text {th }}$ question $A_{n}$ and the answer to this question $Y_{n+1}$.

Lemma 1. On the event $A_{n}=A$ and $Y_{n+1}=y$, the posterior density on $X^{*}$ is

$$
p_{n+1}(u)=\frac{1}{\mathcal{Z}}\left(f_{1}(y) \mathbb{1}_{u \in A}+f_{0}(y) \mathbb{1}_{u \notin A}\right) p_{n}(u)
$$

where

$$
\begin{equation*}
\mathcal{Z}=f_{1}(y) p_{n}(A)+f_{0}(y)\left(1-p_{n}(A)\right) \tag{2}
\end{equation*}
$$

Proof. On the event $A_{n}=A$ and $Y_{n+1}=y$, the posterior density $p_{n+1}(u)=$ $P\left(X^{*} \in d u \mid D_{n+1}\right) / d \lambda=P\left(X^{*} \in d u \mid D_{n}, A_{n}=A, Y_{n+1}=y\right) / d \lambda$, where $\lambda$ is the Lebesgue
measure, can be written using Bayes' formula as

$$
\begin{aligned}
& \frac{1}{\mathcal{Z}}\left[P\left(Y_{n+1} \in d y \mid D_{n}, A_{n}=A, X^{*}=u\right) / d \mu\right]\left[P\left(X^{*} \in d u \mid D_{n}, A_{n}=A\right) / d \lambda\right] \\
& =\frac{1}{\mathcal{Z}}\left(f_{1}(y) \mathbb{1}_{u \in A}+f_{0}(y) \mathbb{1}_{u \notin A}\right) p_{n}(u)
\end{aligned}
$$

where $\mathcal{Z}$ is the normalizing constant, $\mathcal{Z}=\int_{u}\left(f_{1}(y) \mathbb{1}_{u \in A}+f_{0}(y) \mathbb{1}_{u \notin A}\right) p_{n}(u) d u$.
Later, we will take conditional expectations given the density $p_{n}$. Formally, these conditional expectations are taken with respect to the sigma-algebra generated by the stochastic process $\left\{p_{n}(u): u \in I\right\}$. Because $p_{n}(u)$ for each $u$ is a function of $D_{n}$ by the recursive expression in Lemma 1, this sigma-algebra is a subset of the sigma-algebra generated by $D_{n}$.

We will measure the quality of the information gained about $X^{*}$ from these $N$ questions using the Shannon differential entropy. The Shannon differential entropy (see [6] Chapter 9), or simply "the entropy" of $p_{n}, H\left(p_{n}\right)$, is defined as

$$
H\left(p_{n}\right)=-\int_{-\infty}^{+\infty} p_{n}(x) \log p_{n}(x) d x
$$

where $\log$ is the logarithm in base 2. In particular, we consider the problem of finding a sequence of $N$ questions such that the expected entropy of $X^{*}$ after observing the $N^{t h}$ answer is minimized.

We will write this problem more formally as the infimum over policies of the expectation of the posterior entropy, but before doing so we must formally define a policy. Informally, a policy is a method for choosing the questions $A_{n}$ as a function of the observations available at time $n$. The technical assumption that each question $A_{n}$ is a union of only finitely many intervals ensures the Borel-measurability of $H\left(p_{N}\right)$ under each policy.

First, $A_{n}$ is the union of at most $J_{n}$ half-open intervals, and so may be written

$$
A_{n}=\bigcup_{j=1}^{J_{n}}\left[a_{n, j}, b_{n, j}\right)
$$

where $a_{n, j} \leq b_{n, j}$ are elements of $\overline{\mathbb{R}}=\mathbb{R} \cup\{-\infty,+\infty\}$. If $a_{n, j}=-\infty$ then the corresponding interval is understood to be open on the left. Here $J_{0}, J_{1}, \ldots, J_{N-1}$ is any fixed sequence of natural numbers that is the same for all policies. If $A_{n}$ comprises strictly less than $J_{n}$ intervals then we may take $a_{n, j}=b_{n, j}$ for some $j$. When $A_{n}$ is written in this way, the space in which $A_{n}$ takes values may be identified with the space $\mathbb{A}_{n}=\left\{\left(a_{j}, b_{j}\right): j=1, \ldots, J_{n}, a_{j} \leq b_{j}\right\}$, which is a closed subset of $\overline{\mathbb{R}}^{2 J_{n}}$.

Then, with $p_{0}$ fixed, $p_{n}$ may be identified with the sequence $\left(\left(a_{m, j}, b_{m, j}\right)_{j=1}^{J_{m}}, Y_{m+1}\right)_{m=0}^{n-1}$, which takes values in the space $\mathbb{S}_{n}=\left(\mathbb{A}_{0} \times \cdots \times \mathbb{A}_{n-1}\right) \times \mathbb{R}^{n}$. Furthermore, the function $p_{n} \mapsto H\left(p_{n}\right)$ may be written as a measurable function from $\mathbb{S}_{n}$ to $\mathbb{R}$.

Thus, after having identified possible values for $A_{n}$ with points in $\mathbb{A}_{n}$ and possible values for $p_{n}$ with points in $\mathbb{S}_{n}$, we define a policy $\pi$ to be a sequence of functions $\pi=\left(\pi_{0}, \pi_{1}, \ldots\right)$, where $\pi_{n}: \mathbb{S}_{n} \mapsto \mathbb{A}_{n}$ is a measurable function. We let $\Pi$ be the space of all such policies. Any such policy $\pi$ induces a probability measure on
$\left(\left(a_{n, j}, b_{n, j}\right)_{j=1}^{J_{n}}, Y_{n+1}\right)_{n=0}^{N-1}$. We let $E^{\pi}$ indicate the expectation with respect to this probability measure. In a slight abuse of notation, we will sometimes talk of $p \in \mathbb{S}_{n}$ and $A \in \mathbb{A}_{n}$, by which we mean the density $p$ assocatied with a vector in $\mathbb{S}_{n}$, or the set $A$ associated with a vector in $\mathbb{A}_{n}$.

With this definition of a policy $\pi$, the associated measure $E^{\pi}$, and the space of all policies $\Pi$, the problem under consideration may be written,

$$
\begin{equation*}
\inf _{\pi \in \Pi} E^{\pi}\left[H\left(p_{N}\right)\right] \tag{3}
\end{equation*}
$$

Any policy attaining the infimum is called optimal. We consider this problem for the general case in Sec. 3, and for the specific cases of $d=1$ and $d=2$ in Sec. 4 and Sec. 5 respectively. In Sec. 5 , we also consider a modification of this objective function that separately considers the entropy of the marginal posterior distribution, and ensures that both entropies are small. This prevents a policy from obtaining optimality by learning one coordinate of $X^{*}$ without learning the other.

## 3. Entropy Loss and Channel Capacity

In this section we consider the problem (3) of minimizing the expected entropy of the posterior over $\mathbb{R}^{d}$. We present general results characterizing optimal policies, which will be used to create specific policies in Sec. 4 and Sec. 5.

We first present some notation that will be used within our results. Let $\varphi$ be the function with domain $[0,1]$ defined by

$$
\varphi(u)=H\left(u f_{1}+(1-u) f_{0}\right)-u H\left(f_{1}\right)-(1-u) H\left(f_{0}\right) .
$$

$\varphi(u)$ is a mutual information, see (7) and (10). The associated channel capacity $C$ is

$$
C=\sup _{u \in[0,1]} \varphi(u)
$$

Below, in Theorem 1, we show that this maximum is attained in $(0,1)$. Let $u^{*} \in(0,1)$ be a point attaining this maximum, so $\varphi\left(u^{*}\right)=C$.

We show that an optimal policy consists of choosing each $A_{n}$ so that $p_{n}\left(A_{n}\right)=u^{*}$. When the $A_{n}$ are chosen in this way, the expected entropy decreases arithmetically by the constant $C$ at each step. Moreover, if the communication channel is symmetric in the sense that $\varphi(1-u)=\varphi(u), \forall 0 \leq u \leq 1$, then $u^{*}=\frac{1}{2}$. In the noiseless case, or even the case where the support of $f_{0}$ and $f_{1}$ do not overlap, the model is symmetric, $C=1$ and the obvious bisection policy is optimal.

Optimal policies constructed by choosing $p_{n}\left(A_{n}\right)=u^{*}$ are greedy policies (or "knowledge-gradient" policies as defined in [9]), since they make decisions that would be optimal if only one measurement remained, i.e., if $N$ were equal to $n+1$. Such greedy policies are usually used only as heuristics, and so it is interesting that they are optimal in this problem.

Our analysis relies on dynamic programming. To support this analysis, we define the value function,

$$
V(p, n)=\inf _{\pi \in \Pi} E^{\pi}\left[H\left(p_{N}\right) \mid p_{n}=p\right], \quad p \in \mathbb{S}_{n}, n=0, \ldots, N
$$

Standard results from controlled Markov processes show that this value function satisfies Bellman's recursion (Section 3.7 of [8]),

$$
\begin{equation*}
V(p, n)=\inf _{A \in \mathbb{A}_{n}} E\left[V\left(p_{n+1}, n+1\right) \mid A_{n}=A, p_{n}=p\right], \quad p \in \mathbb{S}_{n}, n<N \tag{4}
\end{equation*}
$$

where the expectation is taken over $Y_{n+1}$, and any policy attaining the minimum of (4) is optimal (Section 2.3 of [8]). In general, the results of [8] for general Borel models imply only that $V(\cdot, n): \mathbb{S}_{n} \mapsto \mathbb{R}$ is universally measurable, and do not imply Borelmeasurability. However, we show below in Theorem 2 that, in our case, $V(\cdot, n): \mathbb{S}_{n} \mapsto$ $\mathbb{R}$ is a Borel-measurable function.

As a preliminary step toward solving Bellman's recursion, we present the following theorem, which shows that minimizing the expected entropy of the posterior one step into the future can be accomplished by choosing $A_{n}$ as described above. Furthermore, it shows that the expected reduction in entropy is the channel capacity $C$.

## Theorem 1.

$$
\begin{equation*}
\inf _{A \in \mathbb{A}_{n}} E\left[H\left(p_{n+1}\right) \mid A_{n}=A, p_{n}\right]=H\left(p_{n}\right)-C \tag{5}
\end{equation*}
$$

where the expectation is taken over $Y_{n+1}$. Moreover, there exists a point $u^{*} \in(0,1)$ such that $\varphi\left(u^{*}\right)=C$, and the minimum in (5) is attained by choosing $A$ such that $p_{n}(A)=u^{*}$.

Proof. We first rewrite the expected entropy as

$$
E\left[H\left(p_{n+1}\right) \mid A_{n}=A, p_{n}\right]=H\left(p_{n}\right)-I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right)
$$

where $I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right)$ is the mutual information between the conditional distributions of $X^{*}$ and $Y_{n+1}$ (see [6] Chapter 2), and we have noted that the entropy of $X^{*}$ given $A_{n}=A$ and $p_{n}$ is exactly $H\left(p_{n}\right)$. This leads to

$$
\begin{equation*}
\inf _{A \in \mathbb{A}_{n}} E\left[H\left(p_{n+1}\right) \mid A_{n}=A, p_{n}\right]=H\left(p_{n}\right)-\sup _{A \in \mathbb{A}_{n}} I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right) \tag{6}
\end{equation*}
$$

Temporarily fixing $A$, we expand the mutual information as

$$
\begin{equation*}
I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right)=H\left(Y_{n+1} \mid A_{n}=A, p_{n}\right)-H\left(Y_{n+1} \mid X^{*}, A_{n}=A, p_{n}\right) \tag{7}
\end{equation*}
$$

where $H(. \mid$.$) is the conditional entropy, as defined in [6] Chapter 2. Using (2),$

$$
\begin{equation*}
H\left(Y_{n+1} \mid A_{n}=A, p_{n}\right)=H\left(p_{n}(A) f_{1}+\left(1-p_{n}(A)\right) f_{0}\right) \tag{8}
\end{equation*}
$$

Also,

$$
\begin{align*}
H\left(Y_{n+1} \mid X^{*}, A_{n}=A, p_{n}\right) & =\int_{u} p_{n}(u) H\left(Y_{n+1} \mid X^{*}=u, A_{n}=A, p_{n}\right) d u \\
& =\int_{u \in A} p_{n}(u) H\left(f_{1}\right) d u+\int_{u \notin A} p_{n}(u) H\left(f_{0}\right) d u \\
& =H\left(f_{1}\right) p_{n}(A)+H\left(f_{0}\right)\left(1-p_{n}(A)\right) \tag{9}
\end{align*}
$$

The difference between (8) and (9) is $\varphi\left(p_{n}(A)\right)$, and so

$$
\begin{equation*}
I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right)=\varphi\left(p_{n}(A)\right) \tag{10}
\end{equation*}
$$

This and (6) together show that

$$
\sup _{A \in \mathbb{A}_{n}} I\left(X^{*}, Y_{n+1} \mid A_{n}=A, p_{n}\right)=\sup _{A \in \mathbb{A}_{n}} \varphi\left(p_{n}(A)\right)=\sup _{u \in[0,1]} \varphi(u)=C
$$

This shows (5), and that the infimum in (5) is attained by any set $A$ with $\varphi\left(p_{n}(A)\right)=C$. It remains only to show the existence of a point $u^{*} \in(0,1)$, with $\varphi\left(u^{*}\right)=C$.

First, $\varphi$ is a continuous function, so its maximum over the compact interval $[0,1]$ is attained. If the maximum is attained in $(0,1)$, then we simply choose $u^{*}$ to be this point. Now consider the case when the maximum is attained at $u \in\{0,1\}$. Because $\varphi$ is a mutual information, it is non-negative. Also, $\varphi(0)=\varphi(1)=0$. Thus, if the maximum is attained at $u \in\{0,1\}$, then $\varphi(u)=0$ for all $u$, and one can choose $u^{*}$ in the open interval $(0,1)$.

We are ready now to present the main result of this section, which gives a simple characterization of optimal policies.

Theorem 2. Any policy that chooses each $A_{n}$ to satisfy

$$
\begin{equation*}
p_{n}\left(A_{n}\right)=u^{*} \in \arg \max _{u \in[0,1]} \varphi(u) \tag{11}
\end{equation*}
$$

is optimal. In addition, for each $n$, the value function $V(\cdot, n): \mathbb{S}_{n} \mapsto \mathbb{R}$ is Borelmeasurable and is given by

$$
\begin{equation*}
V\left(p_{n}, n\right)=H\left(p_{n}\right)-(N-n) C . \tag{12}
\end{equation*}
$$

Proof. It is enough to show for each $n=0,1, \ldots, N$ that the value function is given by (12), and that the described policy achieves the minimum in Bellman's recursion (4). Measurability of $V(\cdot, n): \mathbb{S}_{n} \mapsto \mathbb{R}$ then follows from the fact that $p_{n} \mapsto H\left(p_{n}\right)$ is Borel-measurable when written as a function from $\mathbb{S}_{n}$ to $\mathbb{R}$. We proceed by backward induction on $n$. The value function clearly has the claimed form at the final time $n=N$. Now, fix any $n<N$ and assume that the value function is of the form claimed for $n+1$. Then, Bellman's recursion and the induction hypothesis show,

$$
\begin{align*}
V\left(p_{n}, n\right) & =\inf _{A \in \mathbb{A}_{n}} E\left[V\left(p_{n+1}, n+1\right) \mid A_{n}=A, p_{n}\right] \\
& =\inf _{A \in \mathbb{A}_{n}} E\left[H\left(p_{n+1}\right)-(N-n-1) C \mid A_{n}=A, p_{n}\right] \\
& =\inf _{A \in \mathbb{A}_{n}} E\left[H\left(p_{n+1}\right) \mid A_{n}=A, p_{n}\right]-(N-n-1) C  \tag{13}\\
& =H\left(p_{n}\right)-C-(N-n-1) C \\
& =H\left(p_{n}\right)-(N-n) C
\end{align*}
$$

where we have used Theorem 1 in rewriting (13) in the next line. Theorem 1 also shows that the infimum in (13) is attained when $A$ satisfies $p_{n}(A)=u^{*}$, and so the described policy achieves the minimum in Bellman's recursion.

We offer the following interpretation of the optimal reduction in entropy shown in Theorem 2. First, the entropy of a random variable uniformly distributed over $[a, b]$ is $\log (b-a)$. The quantity $2^{H(X)}$ for a continuous random variable $X$ can then be interpreted as the length of the support of a uniform random variable with the same
entropy as $X$. We refer to this quantity more simply as the "length of $X$." If the prior distribution of $X^{*}$ is uniform over [ 0,1 ], then the length of $X^{*}$ under $p_{0}$ is 1 and Theorem 2 shows that the expected length of $X^{*}$ under $p_{N}$ is no less than $2^{-C N}$, where this bound on the expected length can be achieved using an optimal policy.

We conclude this section by discussing $u^{*}$ and $C$ in a few specific cases. In general, there is no simple expression for $u^{*}$ and for $C$. However, in certain symmetric cases the following proposition shows that $u^{*}=\frac{1}{2}$.

Proposition 1. If the channel has the following symmetry

$$
\begin{equation*}
\varphi(u)=\varphi(1-u), \forall 0 \leq u \leq 1 \tag{14}
\end{equation*}
$$

then $\frac{1}{2} \in \arg \max _{u \in[0,1]} \varphi(u)$ and we may take $u^{*}=\frac{1}{2}$. Furthermore, if

$$
\begin{equation*}
H\left(u f_{1}+(1-u) f_{0}\right)=H\left(u f_{0}+(1-u) f_{1}\right) \quad \text { for all } u \in[0,1] \tag{15}
\end{equation*}
$$

then this is sufficient to guarantee (14).
Proof. Let $u^{\prime}$ be a maximizer of $\varphi(u)$. It might be equal to $u^{*}$, or if there is more than one maximizer, it might differ. Note that $\frac{1}{2}=\frac{1}{2} u^{\prime}+\frac{1}{2}\left(1-u^{\prime}\right) . \varphi$ is concave ([6] Chapter 2, Theorem 2.7.4), implying $\varphi\left(\frac{1}{2}\right) \geq \frac{1}{2} \varphi\left(u^{\prime}\right)+\frac{1}{2} \varphi\left(1-u^{\prime}\right)$. Now, using $\varphi\left(u^{\prime}\right)=\varphi\left(1-u^{\prime}\right)$, we obtain $\varphi\left(\frac{1}{2}\right) \geq \varphi\left(u^{\prime}\right)$, which shows that $\frac{1}{2} \in \arg \max _{u \in[0,1]} \varphi(u)$. If (15) is met, then $H\left(f_{0}\right)=H\left(f_{1}\right)$ by taking $u=0$, and (14) follows directly from the definition of $\varphi$.

A few simple channels with expressions for $u^{*}$ and $C$ are presented in Table 1. We use the notation $B(u)$ for a Bernoulli random variable with parameter $u$ and $h(u)$ for $H(B(u))$, the entropy of this random variable. In the multivariate normal case, $u^{*}=\frac{1}{2}$ follows from Proposition 1 because $u f_{1}+(1-u) f_{0}$ is the multivariate normal density with mean $u m_{1}+(1-u) m_{0}$ and variance $\Sigma$, and the entropy of a multivariate normal distribution does not depend on its mean, implying (15) is satisfied.

## 4. 1-Dimensional Optimal Policies

We now present two specific policies in $d=1$ dimension that satisfy the sufficient conditions for optimality given in Theorem 2: the probabilistic bisection policy, and the dyadic policy. After defining these two policies in Sections 4.1 and 4.2, we study the sequence of entropies $\left(H\left(p_{n}\right): n \geq 1\right)$ that they generate, focusing on the dyadic policy. In addition to Theorem 2 , which shows that $E^{\pi}\left[H\left(p_{n}\right)\right]=H\left(p_{0}\right)-n C$ for any optimal policy $\pi$, the analysis of the dyadic policy in Sec. 4.2 provides a strong law of large numbers and a central limit theorem for $H\left(p_{n}\right)$. In further analysis of the dyadic policy, Sec. 4.3 analyzes the number of size-limited noise-free questions required to find $X^{*}$ after noisy questioning with the dyadic policy ceases, which is a metric important in the application discussed in Sec. 6.

To support the analysis in Sections 4.1 and 4.2, we first give here a general expression for the one-step change in entropy, $H\left(p_{n+1}\right)-H\left(p_{n}\right)$, under any policy $\pi$ satisfying $p_{n}\left(A_{n}\right)=u^{*}$.

| Channel | Model |  | Channel Capacity | $u^{*}$ |  |  |
| :--- | :--- | :---: | :---: | :---: | :---: | :---: |
| Binary Symmetric |  |  |  |  |  |  |
|  |  | 0 | 1 |  |  |  |
|  | $f_{0}$ | $1-\epsilon$ | $\epsilon$ | $1-h(\epsilon)$ | $\frac{1}{2}$ |  |
|  | $f_{1}$ | $\epsilon$ | $1-\epsilon$ |  |  |  |

Binary Erasure

|  | 0 | 1 | $e$ |
| :---: | :---: | :---: | :---: |
| $f_{0}$ | $1-\epsilon$ | 0 | $\epsilon$ |
| $f_{1}$ | 0 | $1-\epsilon$ | $\epsilon$ |

$$
\begin{equation*}
1-\epsilon \tag{1}
\end{equation*}
$$

| Z |  | 0 | 1 | $h\left(u^{*}(1-\epsilon)\right)-u^{*} h(\epsilon)$ | $\frac{1 /(1-\epsilon)}{1+e^{h(\epsilon) /(1-\epsilon)}}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |

Table 1: Channel capacity, and the value $u^{*}$ at which the channel capacity is achieved

## Lemma 2.

$$
\begin{align*}
H\left(p_{n+1}\right) & -H\left(p_{n}\right)=-D\left(B\left(\frac{u^{*} f_{1}(y)}{Z}\right), B\left(u^{*}\right)\right) \\
& +\frac{u\left(1-u^{*}\right)}{Z}\left(f_{1}(y)-f_{0}(y)\right)\left(H\left(p_{n}^{+}\right)-\log u^{*}-H\left(p_{n}^{-}\right)+\log \left(1-u^{*}\right)\right) \tag{16}
\end{align*}
$$

where $D$ is the Kullback-Leibler divergence.

Proof. First, we define two densities:

$$
p_{n}^{+}(x)=\left\{\begin{array}{l}
\frac{p_{n}(x)}{u^{*}}, \text { if } x \in A_{n}, \\
0, \text { if } x \in \bar{A}_{n},
\end{array} \quad p_{n}^{-}(x)=\left\{\begin{array}{l}
\frac{p_{n}(x)}{1-u^{*}, \text { if } x \in \bar{A}_{n}} \\
0, \text { if } x \in A_{n}
\end{array}\right.\right.
$$

where $\bar{A}_{n}$ is the complement of $A_{n}$. Their entropies are respectively,

$$
\begin{aligned}
& H\left(p_{n}^{+}\right)=\log u^{*}-\frac{1}{u^{*}} \int_{A_{n}} p_{n}(x) \log p_{n}(x) d x \\
& H\left(p_{n}^{-}\right)=\log \left(1-u^{*}\right)-\frac{1}{1-u^{*}} \int_{\bar{A}_{n}} p_{n}(x) \log p_{n}(x) d x
\end{aligned}
$$

and $H\left(p_{n}\right)=u^{*} H\left(p_{n}^{+}\right)+\left(1-u^{*}\right) H\left(p_{n}^{-}\right)+h\left(u^{*}\right)$.

Using Lemma 1, for a given observation $Y_{n+1}=y$, we have

$$
\begin{aligned}
H\left(p_{n+1}\right)= & \log Z-p_{n+1}\left(A_{n}\right) \log f_{1}(y)-p_{n+1}\left(\bar{A}_{n}\right) \log f_{0}(y) \\
& -\frac{1}{Z} f_{1}(y) \int_{A_{n}} p_{n}(x) \log p_{n}(x) d x-\frac{1}{Z} f_{0}(y) \int_{\bar{A}_{n}} p_{n}(x) \log p_{n}(x) d x \\
= & \log Z-\frac{1}{Z} u f_{1}(y) \log f_{1}(y)-\frac{1}{Z}(1-u) f_{0}(y) \log f_{0}(y) \\
& -\frac{1}{Z} u^{*} f_{1}(y)\left(\log u^{*}-H\left(p_{n}^{+}\right)\right)-\frac{1}{Z}\left(1-u^{*}\right) f_{0}(y)\left(\log \left(1-u^{*}\right)-H\left(p_{n}^{-}\right)\right) .
\end{aligned}
$$

Expanding and rearranging, we obtain (16).
Note also that under an optimal policy, the density of $Y_{n+1}$ is the mixture of densities $u^{*} f_{1}+\left(1-u^{*}\right) f_{0}$ according to Lemma 1 , and the random variables $Y_{1}, Y_{2}, \ldots$ are i.i.d.

### 4.1. Probabilistic Bisection Policy

We first consider the case when questions are limited to intervals $A=(-\infty, a)$, $a \in \mathbb{R}$. This limitation appears naturally in applications such as stochastic root-finding [24] and signal estimation [5]. In this case, an optimal policy consists of choosing $a_{n}$ such that $\int_{-\infty}^{a_{n}} p_{n}(x) d x=u^{*}$. Such an $a_{n}$ always exists but is not necessarily unique.

When the model is symmetric in the sense of Proposition 1, $u^{*}=\frac{1}{2}$, and $a_{n}$ is the median of $p_{n}$. This policy of measuring at the median of the posterior is the probabilistic bisection policy introduced by [12]. Thus, the optimal policy with interval questions and general channels is a generalization of the probabilistic bisection policy, and we continue to refer to it as the probabilistic bisection policy even when $u^{*} \neq \frac{1}{2}$.

We briefly consider the behavior of $\left(H\left(p_{n}\right): n \geq 1\right)$ under the probabilistic bisection policy. We assume a binary symmetric channel with noise parameter $\epsilon$. Recall that $u^{*}=\frac{1}{2}$ in this case, and

$$
\begin{equation*}
D\left(B\left(\frac{f_{1}\left(Y_{n+1}\right)}{2 Z}\right), B\left(\frac{1}{2}\right)\right)=1-h(\epsilon) . \tag{17}
\end{equation*}
$$

Moreover,

$$
H\left(p_{n+1}\right)-H\left(p_{n}\right)=h(\epsilon)-1+\left(\frac{1}{2}-\epsilon\right) W_{n+1}\left(H\left(p_{n}^{+}\right)-H\left(p_{n}^{-}\right)\right.
$$

where the $W_{n}$ are i.i.d Rademacher random variables. In this situation, even when $p_{0}$ is the density of the uniform distribution over the interval $[0,1]$, the behavior of the process $H\left(p_{n}\right)$ can be complicated. A simulation of $H\left(p_{n}\right)$ is presented in Fig. 1. The high degree of variation of $H\left(p_{n}\right)$ around its mean value evident in Fig. 1 may be disadvantageous in some applications. We do not pursue the probabilistic bisection policy further in this paper.

### 4.2. Dyadic Policy

Consider now the situation where all sets in $\mathbb{A}_{n}$ are available as questions, and $p_{0}$ is piecewise constant with finite support. Let $I=\left\{I_{k}: k=0, \ldots, K-1\right\}$ be a finite partition of the support of $p_{0}$ into intervals such that $p_{0}$ is constant and strictly positive in each of these intervals. We assume that each interval $I_{k}$ is closed on the left and

Figure 1: The process $H\left(p_{n}\right)$ for the binary symmetric channel. $p_{0}$ is Uniform $([0,1])$. Top: The questions are chosen by the probabilistic bisection policy. Top Left: $\epsilon=0.2, C=0.28$. Top Right: $\epsilon=0.4, C=0.03$. Bottom: The questions are chosen according to the dyadic policy. Bottom Left: binary symmetric channel $\epsilon=0.2$ Bottom Right: Normal channel. $f_{0} \sim N(-1,1), f_{1} \sim N(1,1) . C=0.47$.
open on the right, so $I_{k}=\left[a_{k}, b_{k}\right)$ with $a_{k} \in \mathbb{R}$ and $b_{k} \in \mathbb{R}$. This assumption is without loss of generality, because if it is not met, we can alter the prior density $p_{0}$ on a set of Lebesgue measure 0 (which does not change the corresponding prior probability measure) to meet it. We also assume that the constants $J_{n}$ used to construct $\mathbb{A}_{n}$ satisfy $J_{n} \geq 2^{n+1} K$. If this restriction is not met, then we are free to increase $J_{n}$ in most applications.

For each $k=0, \ldots, K-1$ we partition $I_{k}$ into two intervals, $A_{0,2 k}$ and $A_{0,2 k+1}$,

$$
\begin{aligned}
A_{0,2 k} & =\left[a_{0,2 k}, b_{0,2 k}\right)=\left[a_{k}, a_{k}+u^{*}\left(b_{k}-a_{k}\right)\right) \\
A_{0,2 k+1} & =\left[a_{0,2 k+1}, b_{0,2 k+1}\right)=\left[a_{k}+u^{*}\left(b_{k}-a_{k}\right), b_{k}\right) .
\end{aligned}
$$

With this partition, the mass $p_{0}\left(A_{0,2 k}\right)=u^{*} p_{0}\left(I_{k}\right)$. The question asked at time 0 is

$$
A_{0}=\bigcup_{k=0}^{K-1} A_{0,2 k},
$$

and $p_{0}\left(A_{0}\right)=u^{*}$.

Figure 2: Illustration of the dyadic policy when $p_{0}$ is uniform on $[0,1]$ and $u^{*}=5 / 8$. The prior is displayed on top. Below, the sets $A_{n, k}$ are illustrated for $n=0,1,2$. Each question $A_{n}$ is the union of the dark grey subsets $A_{n, k}$ for that value of $n$.

We use a similar procedure recursively for each $n=0,1, \ldots$ to partition each $A_{n, k}$ into two intervals, $A_{n+1,2 k}$ and $A_{n+1,2 k+1}$, and then construct the question $A_{n+1}$ from these partitions. Let $K_{n}=2^{n+1} K$ and for $k=0, \ldots, K_{n}-1$ define

$$
\begin{aligned}
A_{n+1,2 k} & =\left[a_{n+1,2 k}, b_{n+1,2 k}\right)=\left[a_{n, k}, a_{n, k}+u^{*}\left(b_{n, k}-a_{n, k}\right)\right), \\
A_{n+1,2 k+1} & =\left[a_{n+1,2 k+1}, b_{n+1,2 k+1}\right)=\left[a_{n, k}+u^{*}\left(b_{n, k}-a_{n, k}\right), b_{n, k}\right) .
\end{aligned}
$$

Then from these, we define the question to be asked at time $n+1$,

$$
A_{n+1}=\bigcup_{k=0}^{K_{n}-1} A_{n+1,2 k}
$$

This construction is illustrated in Fig. 2.
Observe $p_{n+1}\left(A_{n+1,2 k}\right)=u^{*} p_{n+1}\left(A_{n, k}\right)$ implies $p_{n+1}\left(A_{n+1}\right)=\sum_{k=0}^{K_{n}-1} u^{*} p_{n+1}\left(A_{n, k}\right)=$ $u^{*}$ because $\left\{A_{n, k}: k=0, \ldots, K_{n}-1\right\}$ is a partition of the support of $p_{0}$. Thus, this construction satisfies $p_{n}\left(A_{n+1}\right)=u^{*}$, and is optimal. In addition, the sets $A_{0}, \ldots, A_{n-1}$ are constructed without knowledge of the responses, and thus this policy is non-adaptive. This is useful in applications allowing multiple questions to be asked simultaneously. We call this policy the dyadic policy because each question is constructed by dividing the previous question's intervals into two pieces.

We now provide an analysis that leads to a law of large numbers and a central limit theorem for $H\left(p_{n}\right)$ under this policy when $n$ is large. Under the dyadic policy, we have

$$
H\left(p_{n}^{+}\right)=H\left(p_{n}\right)+\log u^{*} \text { and } H\left(p_{n}^{-}\right)=H\left(p_{n}\right)+\log \left(1-u^{*}\right),
$$

which implies, using (16), that

$$
\begin{equation*}
H\left(p_{n+1}\right)-H\left(p_{n}\right)=-D\left(B\left(\frac{u^{*} f_{1}\left(Y_{n+1}\right)}{u^{*} f_{1}\left(Y_{n+1}\right)+\left(1-u^{*}\right) f_{0}\left(Y_{n+1}\right)}\right), B\left(u^{*}\right)\right), \tag{18}
\end{equation*}
$$

where $Y_{n}$ is, as already stated, a sequence of i.i.d random variables with density the mixture $u^{*} f_{1}+\left(1-u^{*}\right) f_{0}$. We read from (18) that $H\left(p_{n}\right)$ is, in this case, a sum of i.i.d
random variables. Moreover, each one is bounded above and below. Indeed,

$$
\begin{aligned}
0 & \leq D\left(B\left(\frac{u^{*} f_{1}\left(Y_{n+1}\right)}{u^{*} f_{1}\left(Y_{n+1}\right)+\left(1-u^{*}\right) f_{0}\left(Y_{n+1}\right)}\right), B\left(u^{*}\right)\right) \\
& \leq \max \left(D\left(B(0), B\left(u^{*}\right)\right), D\left(B(1), B\left(u^{*}\right)\right)\right)
\end{aligned}
$$

implying the bound

$$
\begin{equation*}
\min \left(\log \left(u^{*}\right), \log \left(1-u^{*}\right)\right) \leq H\left(p_{n+1}\right)-H\left(p_{n}\right) \leq 0 \tag{19}
\end{equation*}
$$

For the binary symmetric channel, (18) reduces to a constant, as noted in (17). This proves the following theorem.

Theorem 3. For any piecewise constant $p_{0}$, using the dyadic policy,

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \frac{H\left(p_{n}\right)}{n}=-C \text { a.s. } \tag{20}
\end{equation*}
$$

and

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \frac{H\left(p_{n}\right)+n C}{\sqrt{n}} \stackrel{\mathrm{D}}{=} N\left(0, \sigma^{2}\right), \tag{21}
\end{equation*}
$$

where $\sigma^{2}$ is the variance of the increment $H\left(p_{n+1}\right)-H\left(p_{n}\right)$, and can be computed from the distribution given in (18). A degenerate situation occurs for the binary symmetric channel with noise $\epsilon$. In this case, the sequence $H\left(p_{n}\right)=H\left(p_{0}\right)-n C$ is constant.

The dyadic policy is illustrated in the bottom graphs of Fig 1. $H\left(p_{n}\right)$ is plotted as a function of $n$. The binary symmetric channel model with $\epsilon=0.2$ is shown on the bottom left. The sequence $H\left(p_{n}\right)$ is constant, in sharp contrast with the behavior of $H\left(p_{n}\right)$ for the same model under the probabilistic bisection policy, shown on the top left of the same figure. Finally, a Normal channel is presented on the bottom right.

### 4.3. Expected number of noise-free questions

In this section, we consider an alternative to entropy for measuring performance, which arises in the example considered in Section 6. We suppose that, in addition to the noisy questions previously discussed, we also have the ability to ask a noise-free oracle whether $X^{*}$ lies in a given set, where the sets about which we can ask noise-free questions come from some restricted class, e.g., their size is below a threshold. In Section 6 , the sets about which we can ask noise-free questions correspond to pixels in an image. We suppose that after a fixed number $N$ of noisy questions, we query sets using the noise-free questions until we find $X^{*}$. The loss function that arises naturally in this situation is the expected number of noise-free questions until $X^{*}$ is found.

Given a posterior $p_{N}$ resulting from the first stage of noisy questions, the optimal way in which to ask the noise-free questions is to first sort the available sets about which noise-free questions can be asked, in decreasing order of their probability of containing $X^{*}$ under $p_{N}$. Then, query these sets in this order until $X^{*}$ is found. Observing that $X^{*}$ is not in a particular set alters the probability of the other sets, but does not change the order of these probabilities. Thus it is sufficient to ask the noise-free questions in an order that depends only upon $p_{N}$, and no subsequent information.

We give below in Theorem 4 an explicit expression for the expected number of noise-free questions required after the dyadic policy completes. Before giving this
expression in Theorem 4, we have the following preliminary result. In both this result and Theorem 4, we assume the dyadic policy, a uniform $p_{0}$, and a binary symmetric channel with noise parameter $\epsilon$.
Proposition 2. For each $k \in\left\{0, \ldots, 2^{N}-1\right\}$, let $M_{k}$ be the number of noisy questions $A_{n}$ whose answer has indicated $X^{*} \in A_{N-1, k}$, either via $A_{N-1, k} \subseteq A_{n}$ and $Y_{n}=1$, or $A_{N-1, k} \subsetneq I \backslash A_{n}$ and $Y_{n}=0$. Then, the density of $A_{N-1, k}$ under $p_{N}$ is

$$
|I|^{-1} 2^{N}(1-\epsilon)^{M_{k}} \epsilon^{N-M_{k}}
$$

Furthermore, for each $m \in\{0, \ldots, N\}$, the number of $k$ with $M_{k}=m$ is deterministic, and is equal to $\binom{N}{m}$.

Proof. In the proof, we refer to $A_{N-1, k}$ as $B_{k}$. During noisy questioning, each time an answer indicates $X^{*} \in B_{k}$, we multiply the posterior density on $B_{k}$ by $2(1-\epsilon)$, and each time an answer indicates $X^{*} \notin B_{k}$ we multiply by $2 \epsilon$. Since the prior density was $|I|^{-1}$, the posterior density on $B_{k}$ after all $N$ measurements is $|I|^{-1} 2^{N}(1-\epsilon)^{M_{k}} \epsilon^{N-M_{k}}$.

For each $k \in\left\{0, \ldots, 2^{N}-1\right\}$, let $b_{k n}=\Pi\left\{B_{k} \subseteq A_{n}\right\}$, and define the binary sequence $b_{k}=\left(b_{k 1}, \ldots, b_{k N}\right)$. By construction of the sets $B_{k}$ under the dyadic policy, each $b_{k}$ is unique. Since there are $2^{N}$ possible binary sequences of $N$ bits, and $2^{N}$ sets $B_{k}$, the mapping between $B_{k}$ and $b_{k}$ is a bijection.

Consider a sequence of answers to noisy questions, $Y_{1}, \ldots, Y_{N}$. For each $b_{k}$ define a subset $D_{k}=\left\{n \in\{1, \ldots, N\}: b_{k n}=Y_{n}\right\}$. Each $b_{k}$ defines a unique subset $D_{k}$. Since there are $2^{N}$ subsets and $2^{N}$ sequences $b_{k}$, each subset $D \subseteq\{1, \ldots, N\}$ is equal to some $D_{k}$. Thus, the mapping between $b_{k}$ and $D_{k}$ is a bijection.

Because $M_{k}=\left|D_{k}\right|$, the number of $k$ with $M_{k}=m$ is equal to the number of subsets $D \subseteq\{1, \ldots, N\}$ of size $m$. This number is exactly $\binom{N}{m}$.

Proposition 2 shows that the number of sets $A_{N-1, k}$ with any given posterior density $|I|^{-1} 2^{N}(1-\epsilon)^{m} \epsilon^{N-m}$ is deterministic. Fig. 3(a) shows this posterior probability distribution, after sorting the sets according to their density, for $N=5$ and $\epsilon=0.3$. The expectation under $p_{N}$ of the number of noise-free questions required to find $X^{*}$ depends only upon this sorted posterior probability density, and is thus also deterministic. We now give an expression for this expectation in Theorem 4.
Theorem 4. In each interval $A_{N-1, k}$ for $k=0, \ldots, 2^{N}-1$, assume that there are $\ell$ disjoint equally sized sets about which we can ask noise-free questions. Then the expectation under $p_{N}$ of the number of noise-free questions required to find $X^{*}$ is

$$
\begin{equation*}
\sum_{m=0}^{N}\binom{N}{m}(1-\epsilon)^{m} \epsilon^{N-m}\left[\frac{\binom{N}{m}+1 / \ell}{2}+\sum_{m^{\prime}=m+1}^{N}\binom{N}{m^{\prime}}\right] \ell . \tag{22}
\end{equation*}
$$

Proof. First, if we have a collection of disjoint subsets $C_{1}, \ldots, C_{K}$, each with probability $1 / K$ of containing $X^{*}$, and we query each subset in order of increasing index until we find $X^{*}$, then we ask $k$ questions when $X^{*} \in C_{k}$ and the expected number of questions asked is $\sum_{k=1}^{K} k P\left\{X^{*} \in C_{k}\right\}=\sum_{k=1}^{K} k / K=(K+1) / 2$. Under $p_{N}$, Proposition 2 shows that $X^{*}$ has probability

$$
\begin{equation*}
\binom{N}{m}(1-\epsilon)^{m} \epsilon^{N-m} \tag{23}
\end{equation*}
$$

of being in a subset $A_{N-1, k}$ with $M_{k}=m$, because there are $\binom{N}{m}$ such intervals, each has size $2^{-N}|I|$, and each has density $|I|^{-1} 2^{N}(1-\epsilon)^{m} \epsilon^{N-m}$. Then, because the number of noise-free questions available in each $A_{N-1, k}$ is $\ell$, the expected number of noise-free questions, conditioned on $X^{*}$ being in a subset $A_{N-1, k}$ with $M_{k}=m$, is

$$
\begin{equation*}
\frac{\binom{N}{m} \ell+1}{2}+\sum_{m^{\prime}=m+1}^{N}\binom{N}{m^{\prime}} \ell . \tag{24}
\end{equation*}
$$

Here, the first term is the number of questions asked in subsets with $M_{k}=m$, and the second term is the number asked in subsets with $M_{k}>m$, which had a strictly higher density $p_{N}(x)$ and were queried earlier. Combining (23) and (24) and summing over $k$ shows the result.

Using Theorem 4, we consider the effect of varying $N$. Suppose the sets about which noise-free questions may be asked are pixels in an image, as in the example in Sec. 6. Take $I=[0,1]$ and suppose each pixel is of size $2^{-L}$ and occupies a region $\left[k 2^{-L},(k+1) 2^{-L}\right]$ for some $k=0, \ldots, 2^{L}$. If sets $A_{N-1, k}$ must contain an integer numbers of pixels, then we may naturally consider any $N$ between 0 and $L$. For any such $N$, the number of pixels $\ell$ in a subset $A_{N-1, k}$ is $\ell=2^{L-N}$. In this setting, the expected number of noise-free questions asked as a function of $N$ is shown in Fig. 3(b) for $L=16$ and $\epsilon=0.3$. The figure shows a dramatic decrease in the expected number of noise-free questions as the number of noisy questions $N$ increases.

Figure 3: (a) The posterior density $p_{N}$ for the binary symmetric channel with the dyadic policy, with subsets $A_{N-1, k}$ sorted in order of decreasing posterior density $p_{N}(x)$, and $N=5$.
(b) The expected number of noise-free questions as a function of $N$, for a fixed collection of $2^{16}$ subsets about which noise-free questions may be asked. In both panels, $\epsilon=0.3$.

## 5. Optimal Policies in 2 Dimensions with Entropy Loss

We now consider the case $d=2$, in which $X^{*}$ is a two-dimensional random variable, $X^{*}=\left(X_{1}^{*}, X_{2}^{*}\right)$, with joint density $p_{0}$. To minimize the expected entropy $E\left[H\left(p_{N}\right)\right]$ of the two-dimensional posterior distribution on $X^{*}$ at time $N$, Theorem 2 from Section 3 shows it is optimal to use any policy satisfying $p_{n}\left(A_{n}\right)=u^{*}$.

While the objective function $E\left[H\left(p_{N}\right)\right]$ is natural in $d=1$ dimension, it has a drawback in $d=2$ and higher dimensions. This is well illustrated using an example. Assume that $X_{1}^{*}$ and $X_{2}^{*}$ are independent and uniformly distributed over intervals of lengths $s_{1}$ and $s_{2}$ respectively. Then $H(p)=\log \left(s_{1} s_{2}\right)$. In this case, $H(p)$ can be arbitrarily small even if the entropy of one of the marginal densities remains large, e.g. $s_{2}=1$.

This leads us to consider objective functions without this drawback. For example, we might wish to solve $\inf _{\pi} E^{\pi}\left[\max \left(H_{1}\left(p_{N}\right), H_{2}\left(p_{N}\right)\right)\right]$ where $H_{1}\left(p_{N}\right)=H\left(\int p_{N}\left(\cdot, u_{2}\right) d u_{2}\right)$ and $H_{2}\left(p_{N}\right)=H\left(\int p_{N}\left(u_{1}, \cdot\right) d u_{1}\right)$ are the entropies of the marginals. However, solving this problem directly seems out of reach. Instead, we focus on reducing $E^{\pi}\left[\max \left(H_{1}\left(p_{N}\right), H_{2}\left(p_{N}\right)\right)\right]$ at an asymptotically optimal rate by solving

$$
\begin{equation*}
V(p)=\inf _{\pi} \liminf _{N \rightarrow \infty} \frac{1}{N} E^{\pi}\left[\max \left(H_{1}\left(p_{N}\right), H_{2}\left(p_{N}\right)\right) \mid p_{0}=p\right] \tag{25}
\end{equation*}
$$

We use the liminf to include policies for which the limit might not exist. Throughout this section, we assume that both $H_{1}\left(p_{0}\right)$ and $H_{2}\left(p_{0}\right)$ are finite.

For further simplification, we assume that questions concern only one coordinate. That is, the sets queried are either of type $1, A_{n}=B \times \mathbb{R}$ where $B$ is a finite union of intervals of $\mathbb{R}$, or alternatively of type $2, A_{n}=\mathbb{R} \times B$. In each case, we assume that the response passes through a memoryless noisy channel with densities $f_{0}^{(1)}$ and $f_{1}^{(1)}$ for questions of type 1 , and $f_{0}^{(2)}$ and $f_{1}^{(2)}$ for questions of type 2 . Let $C_{1}$ and $C_{2}$ be the channel capacities for questions of type 1 and 2 respectively. We also assume that $p_{0}$ is a product of its marginals. This guarantees that $p_{n}$ for all $n>0$ remains a product of its marginals and that only one marginal distribution is modified at each point in time. This is shown by the following lemma.
Lemma 3. Assume $p_{n}\left(u_{1}, u_{2}\right)=p_{n}^{(1)}\left(u_{1}\right) p_{n}^{(2)}\left(u_{2}\right)$ and we choose a question of type 1 with $A_{n}=B \times \mathbb{R}$. Then, given $Y_{n+1}=y$,

$$
p_{n+1}\left(u_{1}, u_{2}\right)=\frac{1}{\mathcal{Z}_{1}}\left(f_{1}^{(1)}(y) \mathbb{1}_{\left\{u_{1} \in B\right\}}+f_{0}^{(1)}(y) \mathbb{1}_{\left\{u_{1} \notin B\right\}}\right) p_{n}^{(1)}\left(u_{1}\right) p_{n}^{(2)}\left(u_{2}\right)
$$

where $\mathcal{Z}_{1}=f_{1}^{(1)}(y) p_{n}^{(1)}(B)+f_{0}^{(1)}(y)\left(1-p_{n}^{(1)}(B)\right)$.
Similarly, if we choose a question of type 2 with $A_{n}=\mathbb{R} \times B$ then

$$
p_{n+1}\left(u_{1}, u_{2}\right)=\frac{1}{\mathcal{Z}_{2}}\left(f_{1}^{(2)}(y) \mathbb{1}_{\left\{u_{2} \in B\right\}}+f_{0}^{(2)}(y) \mathbb{1}_{\left\{u_{2} \notin B\right\}}\right) p_{n}^{(2)}\left(u_{2}\right) p_{n}^{(1)}\left(u_{1}\right)
$$

where $\mathcal{Z}_{2}=f_{1}^{(2)}(y) p_{n}^{(2)}(B)+f_{0}^{(2)}(y)\left(1-p_{n}^{(2)}(B)\right)$.
Proof. The proof is straightforward using Bayes formula, and is similar to the proof of Lemma 1 from the 1-dimensional case.

In the 2-dimensional setting, any policy can be understood as making two decisions at each time $n$. The first decision is which coordinate to query, that is, whether to ask a question of type 1 or type 2. Given this choice, the second decision is which question of this type to ask, which corresponds to a finite union of intervals of $\mathbb{R}$. As before, these decisions may depend only upon the information gathered by time $n$, for which the corresponding sigma-algebra is $\mathcal{F}_{n}$. For $N>0$, let $S_{N}$ be the number of questions
of type 1 answered by time $N$. That is, $S_{N}$ is the number of $n \in\{0, \ldots, N-1\}$ such that $A_{n}$ is of the form $A_{n}=B \times \mathbb{R}$. We take $S_{0}=0$.

We first present a lower bound on the expected decrease in the entropy of each marginal posterior distribution.
Lemma 4. Under any valid policy $\pi$,

$$
\begin{aligned}
& E^{\pi}\left[H_{1}\left(p_{n}\right)\right] \geq H_{1}\left(p_{0}\right)-C_{1} E^{\pi}\left[S_{n}\right] \\
& E^{\pi}\left[H_{2}\left(p_{n}\right)\right] \geq H_{2}\left(p_{0}\right)-C_{2}\left(n-E^{\pi}\left[S_{n}\right]\right)
\end{aligned}
$$

Proof. Define $M_{n}^{(1)}=H_{1}\left(p_{n}\right)+C_{1} S_{n}$ and $M_{n}^{(2)}=H_{2}\left(p_{n}\right)+C_{2}\left(n-S_{n}\right)$. We will show that $M^{(1)}$ and $M^{(2)}$ are sub-martingales. Focusing first on $M^{(1)}$, we calculate,

$$
E^{\pi}\left[M_{n+1}^{(1)} \mid \mathcal{F}_{n}\right]=E^{\pi}\left[H_{1}\left(p_{n+1}\right) \mid \mathcal{F}_{n}\right]+C_{1} S_{n+1}
$$

since $S_{n+1}$ is $\mathcal{F}_{n}$-measurable. We consider two cases. First, if $S_{n+1}=S_{n}$ (which occurs if $A_{n}$ is of type 2) then $H_{1}\left(p_{n+1}\right)=H_{1}\left(p_{n}\right)$ and the $\mathcal{F}_{n}$-measurability of $H_{1}\left(p_{n}\right)$ implies $E^{\pi}\left[M_{n+1}^{(1)} \mid \mathcal{F}_{n}\right]=M_{n}^{(1)}$. Second, if $S_{n+1}=S_{n}+1$ (which occurs if $A_{n}$ is of type 1), then Theorem 2 implies

$$
E^{\pi}\left[H_{1}\left(p_{n+1}\right) \mid \mathcal{F}_{n}\right] \geq H_{1}\left(p_{n}\right)-C_{1}
$$

Hence,

$$
E^{\pi}\left[M_{n+1}^{(1)} \mid \mathcal{F}_{n}\right] \geq C_{1}\left(S_{n}+1\right)+H_{1}\left(p_{n}\right)-C_{1}=M_{n}^{(1)}
$$

which shows that $M_{n}^{(1)}$ is a sub-martingale. The proof is similar for $M_{n}^{(2)}$.
Now, because $M_{n}^{(1)}$ is a sub-martingale, $E^{\pi}\left[M_{n}^{(1)}\right] \geq M_{0}^{(1)}$, which implies $E^{\pi}\left[H_{1}\left(p_{n}\right)\right] \geq$ $H_{1}\left(p_{0}\right)-C_{1} E^{\pi}\left[S_{n}\right]$. Proceeding simlarly for $M_{n}^{(2)}$ concludes the proof.

Consider the following policy, notated $\pi^{*}$. At step $n$, choose the type of question at random, choosing type 1 with probability $\frac{C_{2}}{C_{1}+C_{2}}$ and type 2 with probability $\frac{C_{1}}{C_{1}+C_{2}}$. Then, in the dimension chosen, choose the subset to be queried according to the 1 dimensional dyadic policy.

We show below in Theorem 5 that $\pi^{*}$ is optimal for the objective function (25). Before presenting this result, which is the main result of this section, we present an intermediate result concerning the limiting behavior of $\pi^{*}$. This intermediate result is essentially a strong law of large numbers for the objective function (25).

Lemma 5. Let

$$
T_{N}=\frac{1}{N} \max \left(H_{1}\left(p_{N}\right), H_{2}\left(p_{N}\right)\right)
$$

Under $\pi^{*}$, as $N \rightarrow \infty$,

$$
\begin{equation*}
T_{N} \rightarrow-\frac{C_{1} C_{2}}{C_{1}+C_{2}} \text { a.s. } \tag{26}
\end{equation*}
$$

Moreover there is a constant $K$ such that $\left|T_{N}\right|<K$ for all $N$.
Proof. Recall that $S_{N}$ is the number of questions of type 1 answered by time $N$, so $S_{N} / N \rightarrow C_{2} /\left(C_{1}+C_{2}\right)$ a.s. The law of large numbers established in (20) for the one-dimensional posterior shows $H_{1}\left(p_{N}\right) / S_{N} \rightarrow-C_{1}$ a.s. Combining these two facts
shows $H_{1}\left(p_{N}\right) / N \rightarrow-C_{1} C_{2} /\left(C_{1}+C_{2}\right)$ a.s. By a similar argument, $H_{2}\left(p_{N}\right) / N \rightarrow$ $-C_{1} C_{2} /\left(C_{1}+C_{2}\right)$ a.s., which shows (26).

We now show the bound on $\left|T_{N}\right|$. Using $\pi^{*}$, according to (19),

$$
H_{1}\left(p_{N}\right)=H_{1}\left(p_{0}\right)+\sum_{n=1}^{N} Z_{n}
$$

where $Z_{n}$ are independent bounded random variables and $\left|Z_{n}\right| \leq \mid \min (\log (u), \log (1-$ $u)) \mid=\beta$. As a consequence, for any $N \geq 1$,

$$
\left|\frac{H_{1}\left(p_{N}\right)}{N}\right| \leq\left|H_{1}\left(p_{0}\right)\right|+\beta
$$

The same is true for $H_{2}\left(p_{N}\right)$, which proves there is a constant $K$ such that $\left|T_{N}\right|<K$.
We now present the main result of this section.
Theorem 5. The policy $\pi^{*}$ is optimal with respect to (25). Moreover, the optimal value is, for any $p_{0}$ with $H\left(p_{0}\right)<\infty$,

$$
\begin{equation*}
V\left(p_{0}\right)=-\frac{C_{1} C_{2}}{C_{1}+C_{2}} \tag{27}
\end{equation*}
$$

Proof. First we show that the value in (27) constitutes a lower bound for $V\left(p_{0}\right)$. Second, we show (27) is an upper bound on $V\left(p_{0}\right)$ using the properties of the policy $\pi^{*}$ presented in the Lemma 5.

$$
\begin{aligned}
V\left(p_{0}\right) & \geq \inf _{\pi} \liminf _{N \rightarrow \infty} \frac{1}{N} \max \left(E^{\pi}\left[H_{1}\left(p_{N}\right)\right],\left(E^{\pi}\left[H_{1}\left(p_{N}\right)\right]\right)\right. \\
& \geq \inf _{\pi} \liminf _{N \rightarrow \infty} \frac{1}{N} \max \left(H_{1}\left(p_{0}\right)-E\left[S_{N}\right] C_{1}, H_{2}\left(p_{0}\right)-\left(N-E\left[S_{N}\right]\right) C_{2}\right) \\
& =\inf _{0 \leq a \leq 1} \max \left(-a C_{1},-(1-a) C_{2}\right) \\
& =-\frac{C_{1} C_{2}}{C_{1}+C_{2}}
\end{aligned}
$$

We obtain the first line using Jensen inequality, the second line using Lemma 4, the third line by choosing $a=\liminf _{n \rightarrow \infty} E\left[S_{N}\right] / N$ and the fourth line by recalling that $C_{1}>0$ and $C_{2}>0$.

Now, the other equality,

$$
\begin{aligned}
V\left(p_{0}\right) & \leq \liminf _{N \rightarrow \infty} E^{\pi^{*}}\left[\max \left(\frac{H_{1}\left(p_{N}\right)}{N}, \frac{H_{2}\left(p_{N}\right)}{N}\right)\right] \\
& =E^{\pi^{*}}\left[\max \left(\liminf _{N \rightarrow \infty} \frac{H_{1}\left(p_{N}\right)}{N}, \liminf _{N \rightarrow \infty} \frac{H_{2}\left(p_{N}\right)}{N}\right)\right]=-\frac{C_{1} C_{2}}{C_{1}+C_{2}}
\end{aligned}
$$

The uniform bound on $T_{N}$ from Lemma 5 is sufficient to justify the exchange between the limit and the expected value in going from the first to the second line.

We remark as an aside that in the case where $C_{1}=C_{2}$, this policy is also optimal for the value function (3) since it verifies (12).

We conclude this section by providing a central limit theorem for the objective under this policy $\pi^{*}$.
Theorem 6. Under $\pi^{*}$,

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \frac{1}{\sqrt{n}}\left[\max \left(H_{1}\left(p_{n}\right), H_{2}\left(p_{n}\right)\right)+\frac{C_{1} C_{2}}{C_{1}+C_{2}} n\right] \stackrel{\text { 口 }}{=} \frac{\max \left(\sigma_{1} \sqrt{C_{2}} Z_{1}, \sigma_{2} \sqrt{C_{1}} Z_{2}\right)}{\sqrt{C_{1}+C_{2}}} \tag{28}
\end{equation*}
$$

Here, $Z_{1}$ and $Z_{2}$ are independent standard normal random variables, and $\sigma_{i}^{2}$ is the variance of the increment of $H_{i}\left(p_{n+1}\right)-H_{i}\left(p_{n}\right)$ when measuring type $i$, whose distribution is given by (18).

Proof. For $i=1,2$, let $S_{n, i}$ be the number of questions of type $i$ answered by time $n$, so $S_{n, 1}=S_{n}$ and $S_{n, 2}=n-S_{n}$. Let $t_{s, i}=\inf \left\{n: S_{n, i}=s\right\}$ for $s=0,1, \ldots$.. Then $t_{0, i}=0$ and $\left\{t_{s, i}: s=1,2, \ldots\right\}$ are the times when questions of type $i$ are answered. Thus, each stochastic process $\left\{H_{i}\left(p_{t_{s, i}}\right): s=0,1, \ldots\right\}$ for $i=1,2$ has a distribution identical to that of the entropy of the one-dimensional posterior under the dyadic policy. In addition, the two stochastic processes are independent.

The central limit theorem established in (21) shows

$$
\lim _{s \rightarrow \infty} \frac{H_{i}\left(p_{t s, i}\right)+s C_{i}}{\sqrt{s}} \stackrel{\mathrm{D}}{=} \sigma_{i} Z_{i}
$$

where each $Z_{i}$ is a standard normal random variable and $Z_{1}$ is independent of $Z_{2}$.
From the definition of $t_{s, i}$,

$$
\lim _{s \rightarrow \infty} \frac{H_{i}\left(p_{t s, i}\right)+s C_{i}}{\sqrt{s}} \stackrel{\mathrm{D}}{=} \lim _{n \rightarrow \infty} \frac{H_{i}\left(p_{n}\right)+S_{n, i} C_{i}}{\sqrt{S_{n, i}}}
$$

Let $j=1$ when $i=2$, and $j=2$ when $i=1$. Then $\lim _{n \rightarrow \infty} S_{n, i} / n=C_{j} /\left(C_{1}+C_{2}\right)$ a.s. and

$$
\lim _{n \rightarrow \infty} \frac{H_{i}\left(p_{n}\right)+S_{n, i} C_{i}}{\sqrt{S_{n, i}}} \stackrel{\mathrm{D}}{=} \lim _{n \rightarrow \infty} \frac{H_{i}\left(p_{n}\right)+n \frac{C_{1} C_{2}}{C_{1}+C_{2}}}{\sqrt{n}} \sqrt{\frac{C_{1}+C_{2}}{C_{j}}}
$$

These three facts imply,

$$
\lim _{n \rightarrow \infty} \frac{H_{i}\left(p_{n}\right)+n \frac{C_{1} C_{2}}{C_{1}+C_{2}}}{\sqrt{n}} \stackrel{\mathrm{D}}{=} \sqrt{\frac{C_{j}}{C_{1}+C_{2}}} \sigma_{i} Z_{i}
$$

This shows the expression (28) for the limit.

## 6. $\mathrm{IAT}_{\mathrm{E}} \mathrm{X}$ Character Localization

In this section we present an application of the dyadic policy to a well-established problem in computer vision: object localization. While the probabilistic bisection policy has already been applied in computer vision, see [10, 27], the dyadic policy has not, and we feel that it offers considerable promise in this application area.

Figure 4: From left to right: Example of an image containing the character "T". Examples of subset-based questions. In each image, we show the queried region by the gray area, respectively $A_{2}^{1}, A_{2}^{2}$ and $A_{1}^{3}$.

In the object localization problem, we are given an image and a known object, and must output parameters that describe the pose of the object in the image. In the simplest case, the pose is defined by a single pixel, but more complex cases can include, e.g. a rotation angle, a scale factor or a bounding box. Machine learning techniques have led to the development of classifiers that, given a specific pose, provide accurate answers to the binary question "Is the object in this pose?" In our model, we assume these classifiers act as oracles, i.e., are perfect, even though they may occasionally classify incorrectly in practice. Classifiers such as Support Vector Machines [28] and boosting [26] are combined with discriminant features, e.g. [18], to provide the most accurate algorithms, [30, 29]. To find the object's pose within an image, classifiers are evaluated at nearly every possible pose, which is computationally costly. We demonstrate that using the dyadic policy rather than this brute force approach considerably reduces this computational cost. Although a detailed comparison would be beyond the scope of the illustrative example we present here, the branch and bound algorithm used in [17] is an alternative methodology for reducing computational cost in object localization.

## 6.1. $\mathrm{EA}_{\mathrm{E}} \mathrm{X}$ Character Images, Noisy Queries, and Model Estimation

The task we consider is localizing a specific $\mathrm{IA}_{\mathrm{E}} \mathrm{X}$ character in a binary image. In this setting, an image is a binary matrix $I \in\{0,1\}^{m \times m}$, where the image has $m$ rows and $m$ columns. A $\mathrm{IAT}_{\mathrm{E}} \mathrm{X}$ character is another smaller binary image $J \in\{0,1\}^{j \times j}$, where $j<m$. We present experiments where the character of interest, or pattern, is the letter "T". We assume that the pattern is always present in the image, and fully visible (i.e. not occluded by other objects or only partially visible in the image).The goal is to find the location $X^{*}=\left(X_{1}^{*}, X_{2}^{*}\right)$ of the pixel at the upper left corner of the pattern within the image.

We generated 1000 images, each of size $256 \times 256$ pixels. Each image has a black background (i.e. pixel values of zero), and contains a single fully visible "T" at a random location in the image. This " T " is a binary image of size $32 \times 32$ pixels (see Fig. 4(a)). Noise is added to the image by flipping each pixel value independently with probability 0.1 . We then randomly assign each image into one of two sets of approximately equal size: one for training and the other for testing. The training set is used to learn the noise model as described below, and the testing set is used to evaluate the performance of the algorithm.

In this task, querying a set $A$ corresponds to asking whether the upper left corner of the " T " resides in this set. We use a simple image-processing technique to provide
a noisy answer to this question. The technique we use is chosen for its simplicity, and other more complex image-processing techniques might produce more informative responses, improving the overall performance of the algorithm.

In describing this technique, we first observe that all the images are of size $256 \times 256$ pixels and so any pixel coordinate can be represented in base 2 using two 8-bit strings, or octets. For example, the pixel with column-row location $(32,14)$ is represented by $(00100000,00001110)$. We define 16 sets of pixels. Let $A_{1}^{i}, i=1 \ldots, 8$ be the set of pixels whose column pixel coordinate has a 1 for its $i$ th bit. Similarly, let $A_{2}^{i}$, $i=1, \ldots, 8$ be the set of pixels whose row pixel coordinate has a 1 for its $i$ th bit. Fig. 4 (b-d) show the sets $A_{1}^{1}, A_{1}^{2}$ and $A_{2}^{3}$, respectively. For any given image $I$ and set $A_{j}^{i}$, we define the response

$$
\begin{equation*}
y\left(A_{j}^{i}\right)=\sum_{x \in A_{j}^{i}} I(x)-\sum_{x \notin A_{j}^{i}} I(x) \tag{29}
\end{equation*}
$$

where $I(x) \in\{0,1\}$ is the binary image's value at pixel $x$. The motivation for using the response defined by (29) is that $y\left(A_{j}^{i}\right)$ is more likely to be large when $A_{j}^{i}$ contains the "T".

Although the response $y\left(A_{j}^{i}\right)$ is entirely determined by the image $I$ and the location of the " T " within it, our algorithm models the response using a noise model of the form (1). For simplicity, we assume that both the density $f_{1}$ of $y(A)$ when $A$ contains the " T ", and the density $f_{0}$ of $y(A)$ when $A$ does not contain the "T", are normal with respective distributions $N\left(\mu, \sigma^{2}\right)$ and $N\left(-\mu, \sigma^{2}\right)$. The training set is used to estimate these parameters, leading to $\mu=64.76$ and $\sigma=105.7$. Because the model is symmetric, $u^{*}=0.5$. The channel capacity is estimated with Monte Carlo integration to be $C=0.23$.

### 6.2. Prior, Posterior, and Algorithm

We let $X^{*}=\left(X_{1}^{*}, X_{2}^{*}\right), X_{1}^{*} \in[0,255]$ and $X_{2}^{*} \in[0,255]$, with $p_{0}$ uniform over the domain of $X^{*}$. Since the sets $A_{j}^{i}$ constrain only one coordinate, the posterior over $X^{*}$ is a product distribution as was discussed in Sec. 5. The posterior for each coordinate $j=1,2$ was computed in Lemma 3. We now specialize to the model at hand using the notation $\propto$ to define equality up to a term that does not depend on $x_{j}$.

$$
\begin{aligned}
p_{8}^{(j)}\left(x_{j}\right) & \propto \prod_{i=1}^{8}\left(f_{1}\left(y_{j}^{i}\right) \mathbb{1}_{x_{j} \in A_{j}^{i}}+f_{0}\left(y_{j}^{i}\right) \mathbb{1}_{x_{j} \notin A_{j}^{i}}\right) \\
\log p_{8}^{(j)}\left(x_{j}\right) & \propto \sum_{i: x_{j} \in A_{j}^{i}} \log \frac{f_{1}\left(y_{j}^{i}\right)}{f_{0}\left(y_{j}^{i}\right)}
\end{aligned} \sum_{i: x_{j} \in A_{j}^{i}} y_{j}^{i},
$$

The algorithm has two phases: (i) the noisy query phase; and (ii) the noise-free query phase. The noisy query phase comes first, and uses the dyadic policy to obtain a posterior distribution on $X^{*}$. The implementation of this noisy query phase is facilitated by the non-adaptive nature of the dyadic policy's questions, which allows us to compute the answers to the questions all at once. The noise-free query phase then uses the posterior resulting from the first phase, together with a sequence of size-limited noise-free questions, to determine the exact location of $X^{*}$.

Figure 5: Pixel Reordering: (top) Example images from the test set. (bottom) Corresponding $\ell$-images. Dark regions indicate pixels more likely to contain the character, while light regions are less likely.

Noisy Query Phase: Given an image $I$, we begin by computing $y\left(A_{j}^{i}\right)=y_{j}^{i}$, for each $j=1,2$, and $i=1, \ldots, 8$. We then compute $\ell(x)$ for each pixel $x$, which is proportional to the logarithm of the posterior density at $x$,

$$
\ell(x)=\sum_{i: x \in A_{1}^{i}} y_{1}^{i}+\sum_{i: x \in A_{2}^{i}} y_{2}^{i}
$$

Fig. 5(top) shows example images from our test set, while (bottom) shows the corresponding $\ell$-images, in which the value of $\ell(x)$ is plotted for each pixel. Dark regions of the $\ell$-image indicate pixels with large $\ell(x)$, which are more likely to contain the "T".

Noise-free Query Phase: We sort the pixels in decreasing order of $\ell(x)$. We then sequentially perform noise-free evaluations at each pixel $x$ in this order until the true pixel location $X^{*}$ is found. To perform a noise-free evaluation at a given pixel, we compare the "T" pattern with the $32 \times 32$ pixel square from the image with upper left corner at $x$ to see if they match. When $X^{*}$ is found, we stop and record the number of noise-free evaluations performed.

### 6.3. Results

We validated the algorithm above by evaluating it on the test set described in Sec. 6.1. To do this, we ran the algorithm on each image and recorded the number of noise-free evaluations required to locate the target character. The results described below (i) demonstrate that the dyadic policy significantly reduces the number of noisefree evaluations required to locate the "T" character, and (ii) allows us to visualize the results summarized in (12), (20) and (21) within the context of this application.

Recall that each image has $256 \times 256=65,536$ pixels. Over 500 test images, the mean, median and standard deviation of the number of noise-free evaluations are $2021.5,647$ and 4066.9 , respectively. This corresponds to a speed-up factor of 15 over an exhaustive (and typical) search policy. Fig. 6(a) shows the sample distribution of

Figure 6: Noise-free evaluations and convergence in entropy. (a) The distribution of number of noise-free evaluations needed to locate the target character. (b) Plot of $H\left(p_{n}\right) / n$ as a function of $n$. Each line corresponds to one image, with $H\left(p_{n}\right) / n$ plotted over $n=1, \ldots, 16$. $H\left(p_{n}\right) / n$ converges to 1 -C.
the number of noise-free evaluations. We also computed the entropy of the posterior distribution after the 16 noisy questions are answered. According to (12), $E\left[H\left(p_{16}\right)\right]=$ $H\left(p_{0}\right)-16 C=16-16(.23)=12.32$, which is in agreement with the empirically observed value $E\left[H\left(p_{16}\right)\right]=12.3$ (with standard deviation 0.716 ). We also visualized the convergence of the entropy for each image, as predicted by the law of large numbers in (20). In Fig. 6(b), we plot $\frac{H\left(p_{n}\right)}{n}, n=0, \ldots, 16$, for each image in our test set. The empirical variance at $n=16$ is very small. Finally, according to (21), the distribution of $\frac{H\left(p_{n}\right)-\left(H\left(p_{0}\right)-n C\right)}{\sqrt{n}}$ should be approximately normal. Fig. 7(a) shows the histogram and (b) a normal Q-Q plot, demonstrating close agreement with the normal distribution.

## 7. Conclusion

We have considered the problem of 20 questions with noisy responses, which arises in stochastic search, stochastic optimization, computer vision, and other application areas. By considering the entropy as our objective function, we obtained sufficient conditions for Bayes optimality, which we then used to show optimality of two specific policies: probabilistic bisection and the dyadic policy. This probabilistic bisection policy generalizes a previously studied policy, while we believe that the dyadic policy has not been previously considered.

The dyadic policy asks a deterministic set of question, despite being optimal among fully sequential policies. This lends it to applications that allow multiple questions to be asked simultaneously. The structure of this policy also lends itself to further analysis. We provided a law of large numbers, a central limit theorem, and an analysis of the number of noise-free questions required after noisy questioning ceases. We also showed that a generalized version of the dyadic policy is asymptotically optimal in two dimensions for a more robust version of the entropy loss function. We then demonstrated the use of this policy on an example problem from computer vision.

A number of interesting and practically important questions present themselves for future work. First, our optimality results assume the entropy as the objective, but in

Figure 7: Central Limit Theorem: (a) Distribution of $\frac{H\left(p_{n}\right)-\left(H\left(p_{0}\right)-n C\right)}{\sqrt{n}}$, with mean -0.01 . The distribution is close to Gaussian as the Q-Q plot (b) shows.
many applications other objectives are more natural, e.g., the expected number of noisefree questions as in Section 4.3, or mean-squared error. Second, our results assume that noise is added by a memoryless transmission channel. In many applications, however, the structure of the noise depends upon the questions asked, which calls for generalizing the results herein to this more complex style of noise dependence. We feel that these and other questions will be fruitful areas for further study.
