Communication complexity
Circuit complexity
Data structures
Cryptography and pseudo-random numbers

It is not surprising that computer science is perhaps the most important field of applications of combinatorial ideas. Modern computers operate in a discrete fashion both in time and space, and much of classical mathematics must be "discretized" before it can be implemented on computers as, for example, in the case of numerical analysis. The connection between combinatorics and computer science might be even stronger than suggested by this observation; each eld has profited from the other. Combinatorics was the first field of mathematics where the ideas and concepts of computer science, in particular complexity theory had a profound impact. This framework for much of combinatorics has been surveyed in Chapter In this chapter, we illustrate what computer science profits from combinatorics: we have collected a number of examples, all of them rather important in computer science, where methods and results from classical discrete mathematics play a crucial role. Since many of these examples rely on concepts from theoretical computer science that have been discussed in Chapter the reader is encouraged to refer to that chapter for background material.

Communication complexity

There are many situations where the amount of communication between two processors jointly solving a certain task is the real bottleneck; examples range from communication between the earth and a rocket approaching Jupiter to communication between

different parts of a computer chip. We shall see that communication complexity also plays an important role in theoretical studies, and in particular, in the complexity theory of circuits. Other examples of such indirect applications of communication complexity include bounds on the depth of decision trees (Hajnal, Maass and Turán and pseudorandom number generation (Babai, Nisan and Szegedy Communication complexity is a much simpler and cleaner model than computational or circuit complexity and it illustrates notions from complexity theory like non-determinism and randomization in a particularly simple way.O ur interest in this field also stems from the many ways in which it relates to combinatorial problems and methods. This section gives just a glimpse of this theory; see Lovász for a broader survey

Suppose that there are two players, Alice and Bob, who want to evaluate a function $f\ x, y)$i n two variables; for simplicity,w e assume that the value of f is a single bit. Alice knows the value of the variable x Bob knows the value of the variable y and they can communicate with each other Local computation is free, but communication is costly What is the minimum number of bits that they have to communicate?

We can describe the problem by a matrix as follows. Let $a \quad ,a_N$ be the possible inputs of Alice and $b \quad ,b_M$ the possible inputs of Bob. Note that since local computation is free, we need not worry about how these are encoded. Let $c_{ij} \quad f\ a_i,b_j$ The matrix $C \quad c_{ij}\ _i^N\ _j^M$ determines the communication problem. Both players know the matrix C Alice also knows the index i of a row, Bob knows the index j of a column, and they want to determine the entry c_{ij}

To solve their task for a particular matrix C Alice and Bob, before learning their inputs i and j agree in advance on a **protocol** which is the communication analogue to the fundamental notion of an algorithm in computational complexity theory Informally a **communication protocol** is a set of rules specifying the order and meaning" of the messages sent. The protocol prescribes each action for Alice and Bob: who is to send the first bit; depending on the input of that processor, what this bit should be depending on this bit, who is to send the second bit, and depending on the input of that processor and on the first bit sent, what this second bit should be, and so on. The protocol terminates when one processor knows the output bit and the other one knows this about the first one. The **complexity** of a protocol is the number of bits communicated in the worst case.

The **trivial protocol** is that Alice tells her input to Bob. We shall see that sometimes there is no better protocol than this trivial one. This protocol takes $\lceil \log\ N \rceil$ bits; if $M< N$ then the reverse trivial protocol is clearly better. (For the remainder of this chapter, we shall use log to denote log

A protocol has the following combinatorial description in terms of the matrix. First, it determines who sends the first bit; say Alice does. This bit is determined by the input of Alice; in other words, the protocol partitions the rows of the matrix C into two classes, and the first bit of Alice tells Bob which of the two classes contains her row. From now on the game is limited to the submatrix C formed by the rows in this class. Next, the protocol describes a partition of either the rows or columns of C into two classes, depending on who is to send the second bit, and the second bit itself specifies which of these two classes contains the line (row or column) of the sender. This limits the game to a submatrix C and so it continues.

If the game ends after k bits then the remaining submatrix C_k is the union of an all-1 submatrix and an all-0 submatrix. We shall call this an **almost-homogeneous matrix** If, for example, Alice knows the answer, then her row in C_k must be all-0 or all-1, and since Bob knows for sure that Alice knows the answer, this must be true for every row of C_k

We can therefore characterize the communication complexity by the following combinatorial problem: given a matrix C,i n how many rounds can we partition it into almost-homogeneous submatrices, if in each round we can split each of the current submatrices into two either horizontally or vertically). We shall denote this number by C

If rk(C denotes the rank of C then the following inequality observed by Mehlhorn and Schmidt relates the communication complexity to the rank of the matrix:

Lemma. *Over any field,* log rk(C C rk(C ∎

(The lower bound is tightest if we use the real field, whereas the upper bound might be tightened by considering a nite field.)

In particular, we obtain that if C has full row rank then the trivial protocol is optimal. This corollary applies directly to a number of communication problems, of which we mention three. Suppose that Alice knows a subset X of an n-element set S and Bob knows a subset Y of S.T he **equality problem** is to decide if the two subsets are equal; the **disjointness problem** is to decide if the two subsets are disjoint; the **binary inner product problem** is to decide if the intersection of the two sets has odd cardinality In the first two cases, it is trivial to see that the corresponding ^{n} ^{n} matrices have full rank; in the third case, the rank of the matrix is ^{n} Hence the trivial protocols are optimal. (It is interesting to remark that in the third case, the rank over GF(2), which might seem more natural to use in this problem, gives a very poor bound here: the GF(2) rank of C is only n

The lower bound in the lemma is often sharp; on the other hand, no communication problem is known for which C)i s anywhere near the bound rk(C In particular, it is open whether C can be bounded by any polynomial of log rk(C

To point out that the situation is not always trivial, consider again the equality problem. Recall that if N denotes the number of inputs, then the trivial protocol takes $\lceil \log N \rceil$ bits, and this is optimal.

In contrast, Freivalds obtained the very nice result that if Alice and Bob tolerate errors occurring with probability2 then the situation changes drastically Consider the following protocol, which can be viewed as an extension of a parity check". Treat the inputs as two natural numbers x and y x, y N Alice selects a random prime p (log N computes the remainder x of x modulo p and then sends the pair x ,p)t o Bob. Bob then computes the remainder y of y modulo p and compares it with x .I f they are distinct, he concludes that x y if they are the same, he concludes that x y

If the two numbers x and y are equal then, of course, so are x and y and so the protocol reaches the right conclusion. If x and y are different, then it could happen that x y and so the protocol reaches the wrong conclusion. This happens if and only if p is a divisor of x y Since $|x \quad y| < N$ it follows that x y has fewer than log N different prime

divisors. On the other hand, Alice had about (log N log log N primes from which to choose, and so the probability that she chose one of the divisors of x y tends to For N sufficiently large, the error will be smaller than Clearly this protocol uses at most log log N bits.

Randomization need not lead to such dramatic improvements for all problems. We have seen that the binary inner product problem and the disjointness problem behave quite similarly to the equality problem from the point of view of deterministic communication complexity: the corresponding matrices have essentially full rank and hence the trivial protocols are optimal. But, unlike for the equality problem, randomization is of little help here: Chor and Goldreich proved that the randomized communication complexity of computing the binary inner product problem is n Improving results of Babai, Frankl and Simon XXX showed that the randomized communication complexity of the disjointness problem is n The proofs of these facts combine the work of Yao on randomized communication complexity with rather involved combinatorial considerations.

Just as in computational complexity theory non-determinism plays a crucial role in communication complexity theory Non-deterministic protocols were introduced by Lipton and Sedgewick Perhaps the best way to view a non-deterministic protocol is as a scheme by which a third party,k nowing both inputs, can convince Alice and Bob what the value of f is. Again, we want to minimize the number of bits such a **certificate** contains for the worst inputs. For example, if in the disjointness problem the two subsets are not disjoint, announcing a common element convinces both players that the answer is "no". This certificate takes only $\lceil \log n \rceil$ bits, which is much smaller than the number of bits Alice and Bob would need to nd the answer, which is n,a s we have seen On the other hand, if the sets are disjoint, then no such simple non-deterministic scheme exists. We shall distinguish between the non-deterministic protocol for the and for the In both cases, there is always the trivial protocol that announces the input of Alice.

To give a formal and combinatorial description of non-deterministic protocols, consider a non-deterministic protocol for a particular certificate p and those entries of C (i.e., inputs for Alice and Bob) for which this certificate "works". If the proof scheme is correct, these must be all 1's; from the fact that Alice and Bob have to verify the certificate independently,w e also see that these 1's must form a submatrix. Thus, a non-deterministic protocol corresponds to a covering of C by all-1 submatrices. Conversely every such covering gives a non-deterministic protocol: one can simply use the name of the submatrix containing the given entry as a certificate. The number of bits needed is the logarithm of the number of different certificates used: the non-deterministic communication complexity C of a matrix C is the least natural number t such that the 1's in C can be covered by at most2 ^{t} all-1 submatrices. One can analogously define C the non-deterministic communication complexity of certifying a

Note that the all-1 submatrices in the covering need not be disjoint. Therefore, there is no immediate relation between rk C and C It is easy to formulate the non-deterministic communication complexity of a matrix as a set-covering problem: consider the hypergraph whose vertices are the 1's in C and whose edges are the all-1 submatrices; C is the logarithm of the minimum number of edges covering all vertices. An immediate

lower bound on C follows from a simple counting argument: if C has a 1's but each all-1 submatrix of C has at most b entries, then trivially $C \log a \log b$ We can also consider the natural dual problem: if is the maximum number of 1's in C such that no two occur in the same all-1 submatrix, then $C \log$

Returning to the three problems on two sets mentioned above, we see that the 1's in the ^{n} ^{n} identity matrix cannot be covered by fewer that ^{n} all-1 submatrices; hence the non-deterministic communication complexity of equality is n Similarly the non-deterministic communication complexity of set disjointness is n since ^{n}.F or the binary inner product problem, it is easy to see by elementary linear algebra that an all-1 submatrix has at most ^{n} entries, and that exactly ^{n} ^{n} entries are 1's. This gives that at least ^{n} all-1 submatrices are needed to cover the 1's, and so C n For this matrix, a similar argument also shows that C n

We have derived the following lower bound on the communication complexity of a matrix:

$$\max \log \mathrm{rk}(C \quad C \quad C \quad C$$

The identity matrix shows that might be a very weak bound: C can be exponentially large compared with C Interchanging the roles of and we obtain that C might also be very far from C No such example is known for $\log \mathrm{rk}(C$ but it is likely that the situation is similar.

However, it is a surprising fact that the product of any two of these three lower bounds is an upper bound on the communication complexity The first part of the following theorem is due to Aho, Ullman and Yannakakis and the other two, to Lovász and Saks

Theorem. *For every matrix C*

(a) C C C

(b) C $\lfloor \log \mathrm{rk}(C \rfloor$ C

(c) C $\lfloor \log(\mathrm{rk}(C \rfloor$ C

We shall sketch a result that is stronger than each of (a), b) and (c). Let C denote the size of the largest square submatrix of C such that, after a suitable reordering of the rows and columns, each diagonal entry is but each entry above the diagonal is It is clear that C $\mathrm{rk}(C)$a nd C ^{1} C If we define C analogously,t hen C $\mathrm{rk}(C$ By using these inequalities, we can obtain all three parts of Theorem from the following result.

Theorem. C $\lfloor \log$ $C \rfloor$ C

Proof. We use induction on C If C then trivially C Assume that C and let k C then the elements of C can be covered by all-0 submatrices C $,C_l$ where l ^{k} Let A_i denote the submatrix formed by those rows of C that meet C_i and let B_i denote the analogous submatrix formed from columns of C Observe that

$$A_i \quad B_i \quad C \quad i \quad ,l$$

this will play a crucial role in the following protocol.

First, Alice looks at her row to see if it intersects any submatrix C_i with A_i C If so, she sends a and the name i of such a submatrix. They have thereby reduced the problem to the matrix A_i If not, she sends a

When Bob receives this he looks at his column to see if it intersects any submatrix C_i with B_i C If so, he sends a and the name i of such a submatrix. They have thereby reduced the problem to the matrix B_i If not, he sends a

If both Alice and Bob failed to find an appropriate submatrix, then by the intersection of their lines cannot belong to any C_i and so it must be a They have found the answer. ∎

Theorem 1.2(a) has an interesting interpretation. Define a **communication problem** as a class $\mathcal{H}$ of matrices; for simplicity assume that they are square matrices. The communication complexity of any N N matrix is at most $\log N$ We say that $\mathcal{H}$ is in $\mathcal{P}_{\rm comm}$ if it can be solved substantially better: if there exists a constant $c>$ 0s uch that C $(\log\log N^{\ c}$ for each N N matrix $C \in \mathcal{H}$ Similarly,w e say that $\mathcal{H}$ is in $\mathcal{NP}_{\rm comm}$ if there exists a constant $c>$ 0s uch that for each $C \in \mathcal{H}$ C $(\log\log N^{\ c}$,a nd define co-$\mathcal{NP}_{\rm comm}$ analogously based on C Just as for the analogous computational complexity classes, we have the trivial containment

$$\mathcal{P}_{\rm comm} \subseteq \mathcal{N}\,\mathcal{P}_{\rm comm} \quad \text{co–}\mathcal{NP}_{\rm comm}$$

However, for the communication complexity classes we also have the following, rather interesting facts:

$$\mathcal{P}_{\rm comm} \quad \mathcal{NP}_{\rm comm}$$

$$\mathcal{NP}_{\rm comm} \quad \text{co–}\mathcal{NP}_{\rm comm}$$

which follow from the equality problem, but

$$\mathcal{P}_{\rm comm} \quad \mathcal{NP}_{\rm comm} \quad \text{co–}\mathcal{NP}_{\rm comm}$$

by Theorem 1.2(a). This idea was developed by Babai, Frankl and Simon who defined and studied communication analogues of many other well-known complexity classes such as# $\mathcal{P}$ $\mathcal{PSPACE}$ and $\mathcal{BPP}$

Our previous examples were trivial from the point of view of communication: the trivial protocols are optimal. This is quite atypical. Let us define a **round** in the protocol as a maximal period during which one player sends bits to the other. The trivial protocol consists of one round. Let $^{k}\,C$ denote the minimum number of bits needed by a com munication protocol with at most k rounds. Halstenberg and Reischuk proved that for every k there exist arbitrarily large matrices C such that $^{k}\,C$ is exponentially larger than $^{k}\ C$

We consider two combinatorial examples to illustrate that protocols can be significantly more efficient than the trivial ones. Yannakakis considered the following problem: Alice and Bob are given a graph G on n nodes, Alice is given a stable set A and

Bob is given a clique B they must decide whether these sets intersect. The corresponding matrix C has rank n but size exponential in n and so the trivial protocol takes n bits. (Recall that we always focus on the worst-case complexity On the other hand, the non-deterministic communication complexity of non-disjointness is $\log n$ since the name of a common node of A and B is a certificate; by Theorem C $\log n$ (The number of rounds in the protocol is $O(\log n$ It is not known whether the deterministic complexity,o r even the non-deterministic complexity of disjointness, is smaller, such as $O(\log n$ It is interesting to remark that the latter question is equivalent to the following purely graph-theoretic question: is there a constant $c>$ 0s o that in each graph G on n nodes, there exist n^c cuts such that each pair of disjoint sets U, V,w here U is a stable set and V is a clique, is separated by one of these cuts.

In the **subtree disjointness problem** there is a tree T known to both players. Alice gets a subtree T_A and Bob gets a subtree T_B and their task is to decide whether T_A and T_B are node-disjoint. It can be shown that the corresponding matrix C has rank n but has exponential size. The non-deterministic complexity of non-disjointness is $\log n$,a nd hence by Theorem C $\log n$ In this case, one can do better by using the following simple protocol: Alice sends any node x of her tree to Bob. If y is the node in Bob's tree that is closest to x Bob responds by sending y to Alice. Then Alice checks if y T_A if so, then clearly the subtrees are not disjoint; if not, the subtrees are disjoint. This protocol uses $\log n$ bits. Lovász and Saks showed that it can be modified to use only $\log n$ $\log\log n$ bits.

An interesting and rather general class of communication problems, for which good bounds on the complexity can be obtained by non-trivial combinatorial means, was formulated by Hajnal, Maass and Turán Let $\mathcal{L}$ be a finite lattice. Assume that Alice is given an element $a \in \mathcal{L}$ and Bob is given an element $b \in \mathcal{L}$ and their task is to decide whether a b the minimal element of the lattice.

This problem generalizes both the disjointness problem (where $\mathcal{L}$ is a Boolean algebra), and the subtree disjointness problem where $\mathcal{L}$ is the lattice of subtrees of a tree). A third special case worth mentioning is the following **spanning subgraph problem** Alice is given a graph G_A and Bob is given a graph G_B on the same set of nodes V they wish to decide whether G_A G_B is connected. This case relies on the lattice of partitions of V but "upside down" so that the indiscrete partition is Alice can compute the partition a of V into the connected components of G_A Bob can compute the partition b of V into the connected components of G_B and then they decide whether a b

For a given lattice $\mathcal{L}$,l et C be the matrix associated with the corresponding problem: its rows and columns are indexed by the elements of $\mathcal{L}$,a nd c_{ij} if and only if i j To find the rank of this matrix, we give the following factorization of it, using the Möbius function of $\mathcal{L}$ (see Chapter for the definition and some basic properties). Let Z z_{ij} be the zeta-matrix of the lattice, i.e., let z_{ij} if and only if i j $i, j \in \mathcal{L}$ Let D d_{ij} denote the diagonal matrix defined by d_{ii} $,i$ Then it is easy to verify the following identity found by Wilf and Lindström (see Chapter

$$C \quad Z^T D Z$$

Since Z is trivially non-singular, this implies that

$$\mathrm{rk}(C) = \mathrm{r\ k}\ D \quad |\{i \quad ,i \quad\}|$$

This gives a lower bound on the communication complexity of our problem, but how good is this bound? One case when this bound is tight occurs when ,i for all i We obtain a lower bound of $\lceil \log |\mathcal{L}| \rceil$ which is also the upper bound achieved by the trivial protocol; that is, the trivial protocol is optimal. By Corollary of Chapter this case occurs when $\mathcal{L}$ is a geometric lattice or a geometric lattice upside down". In particular, we see that for the spanning subgraph problem, the trivial protocol is optimal.

It turns out that the lower bound given by $\log \mathrm{rk}(C$ is not too far from the truth for any lattice.

Theorem. *For every lattice* $\mathcal{L}$

$$\log \mathrm{rk}(C \qquad C \qquad \log \mathrm{rk}(C$$

Proof (upper bound). Observe that a non-deterministic certificate of non-disjointness of two elements $a, b \in \mathcal{L}$ can be provided by exhibiting an atom of the lattice below both a and b Hence the logarithm of the number of atoms is an upper bound on C Since for every atom i ,i it follows from the identity that the number of atoms is at most $\mathrm{rk}(C$ Hence, the upper bound follows directly from Theorem ∎

Circuit complexity

One promising approach to proving lower bounds on the computational complexity of a problem focuses on the Boolean circuit model of computation, and recent results in this area are possibly the deepest applications of combinatorial methods to computer science thus far. The best way to view a circuit is not as an abstract electronic device; instead, view it as the bit-operational skeleton of any computational procedure ° MR7 this way,i t is not hard to see that this model is equivalent to other models such as the Turing machine or RAM, and that the number of functional elements, or gates, in a circuit is equivalent to the time taken by an algorithm in those models. (More precisely a RAM algorithm, for example, is equivalent to a family of Boolean circuits, one for each input length.) As a result, the extremely difficult task of proving lower bounds on the computational complexity of a given problem can be posed in a way much more suited to combinatorial methods. Many people believe that this is the direction of research that may eventually lead to the solution of famous problems, such as $\mathcal{P}$ vs. $\mathcal{NP}$ Unfortunately the handful of results obtained at this point are rather difficult, and yet quite far from this objective.

Let us recall some definitions from Chapter A **Boolean circuit** is an acyclic directed graph; nodes of indegree are called **input gates** and are labelled with the input variables x x_n nodes with outdegree are called **output gates**;e very node with indegree $r>$ is called a **functional gate** and is labelled with a Boolean function in r variables, corresponding to the predecessors of the node. For our purposes, it suffices

to allow only the logical negation, conjunction, and disjunction as functions. The number of gates in a circuit is called its **size**;t he **circuit complexity** of a problem is the size of the smallest circuit that computes this Boolean function. The outdegree and indegree of a node are referred to as its **fan-out** and **fan-in** respectively

Another important parameter of a circuit is its **depth** the maximum length of a path from an input gate to an output gate. A circuit can also be viewed as parallel algorithm, and then the depth corresponds to the (parallel) time that the algorithm takes. Note that every Boolean function can be computed by a Boolean circuit of depth this is easily derived from its conjunctive normal form. Of course, the number of gates, which is essentially the number of terms in this normal form, is typically exponential.

A circuit is **monotone** if only conjunctions and disjunctions are allowed as functional gates. Note that every monotone increasing Boolean function can be computed by a monotone Boolean circuit.

The predominant approach to proving circuit complexity lower bounds is to restrict the class of allowed circuits. Two kinds of restrictions have proved sufficiently strong, and yet reasonably interesting, to allow the derivation of superpolynomial lower bounds on the number of gates: monotonicity and bounding the depth. Two main methods seem to emerge: the random restriction method and the approximation method Both methods have applications for both kinds of restricted problems.

The rst superpolynomial lower bound in a restricted model of computation concerned constant-depth circuits. Note that for this class of circuits to make sense, we must allow that the gates have arbitrarily large fan-out and fan-in. Furst, Saxe and Sipser and Ajtai proved independently that every constant-depth circuit computing the parity function has superpolynomial size; the **parity** function maps x $,x_n$ x x_n where here, and throughout this section, addition is the mod sum. Yao established a truly exponential lower bound by extending the techniques of Furst, Saxe and Sipser. Hastad has further strengthened the bound and greatly simplified the proof. All of these proofs are based on probabilistic combinatorial arguments; the proof of the following theorem can be found in Chapter

Theorem. *If C is a circuit with n input bits and depth d that computes the parity function, then C has at least* $n^{1 (d 1)}$ *gates.* ∎

Razborov gave an exponential lower bound on the size of constant-depth circuits that compute another simple Boolean function, the so-called **majority function** i.e., the function

$$f\ x \quad ,x_n \qquad \text{if at least } n/2 \text{ o f the } x_i \text{ are}$$
$$\text{otherwise.}$$

In fact, he proved a stronger result by allowing circuits that may have **parity gates**,i n addition to the usual AND OR and NOT gates, where a parity gate computes the parity of the number of 's in its input. The proof uses the **approximation method**,w hich was first used by Razborov 1985a) in his pathbreaking paper on monotone circuits. The later

application of the method is perhaps the cleanest, and we are able to reproduce the full proof.

Theorem. *If C is a circuit of depth d with* AND OR NOT *and parity gates that computes the majority function of n input bits, then C has at least $n^{(1\ 2d)}$ $\sqrt{n}$ gates.*

Proof. Consider a circuit that computes the majority function. We can assume without loss of generality that the circuit uses only parity and OR gates, since these can be used to simulate both AND and NOT gates within constant depth. The idea of the proof is to introduce "approximations" of the gates used during the computation. Using the approximate gates, instead of the real gates, one computes an approximation of the majority function. The quality of the approximation will be measured in terms of the number of inputs on which the modified circuit differs from the original. The main point of the approximation is to keep the computed function "simple" in some sense. We will show that every "simple" function, and in particular the approximation we compute, differs from the majority function on a significant fraction of the inputs. Since the approximation of each gate has a limited effect on the function computed, we can conclude that many approximations had to occur.

Each Boolean function can be expressed as a polynomial over the two-elementfi eld GF The measure of simplicity of a Boolean function f for this proof is the degree of the polynomial representing the function or for short, the **degree of the function**

In fact, the approximation technique is applied not to the majority function, but to a closely related function, the k **threshold function** f_k This function is when at least k of the inputs are It is easy to see that if there is a circuit of size s that computes the majority function of n 1e lements in depth d then, for each k k n,t here is a circuit of depth d and size at most s that computes the k-threshold function on n elements. Therefore, any exponential lower bound for f_k implies a similar bound for the majority function. We shall consider k $\lceil n$ h $\rceil$ for an appropriate h

First we show that any function of low degree has to differ from the k-threshold function on a significant fraction of the inputs.

Lemma. *Let $n/$ k n Every polynomial with n variables of degree h k n differs from the k-threshold function on at least $\binom{n}{k}$ inputs.*

Proof. Let g be a polynomial of degree h and let $\mathcal{B}$ denote the set of vectors where it differs from f_k.L et $\mathcal{A}$ denote the set of all vectors of length n containing exactly k 1's.

For each Boolean function f consider the summation function $f\ x$ $\sum_y\ _x f\ y$ It is trivial to see that the summation function of the monomial x_{i_1} x_{i_r} is for the incidence vector of the set $\{i$ $i_r\}$ and on all other vectors. Hence it follows that f has degree at most h if and only if f vanishes on all vectors with more than h 1's. In contrast to this, the summation function of the k-threshold f_k is on all vectors with fewer than k 1's, but on all vectors with exactly k 1's.

Consider the matrix M m_{ab} whose rows are indexed by the members of $\mathcal{A}$,w hose columns are indexed by the members of $\mathcal{B}$ and

$$m_{ab} \quad \text{if } a \quad b \quad \text{otherwise.}$$

We want to show that the columns of this matrix generate the whole linear space. This will imply that $|\mathcal{B}| \quad |\mathcal{A}| \quad \binom{n}{k}$

Let $a \ ,a \ \in\mathcal{A}$ and let $a \quad a$ denote their coordinatewise minimum. Then we have, by the definition of $\mathcal{B}$

$$\sum_{\substack{b \ a_1 \\ b\in\mathcal{B}}} m_{a_2 b} \qquad \sum_{\substack{b \ a_1 \ a_2 \\ b\in\mathcal{B}}} \qquad \sum_{u \ a_1 \ a_2} f_k \ u \qquad g \ u \qquad \sum_{u \ a_1 \ a_2} f_k \ u \qquad \sum_{u \ a_1 \ a_2} g \ u$$

The second term of this last expression is since $a \quad a$ contains at least $h \quad 1$'s. The first term is also except if $a \quad a$ The columns of M therefore generate the unit vector corresponding to the coordinate a and so they generate the whole space. ∎

If p and p are polynomials representing two functions, then $p \quad p$ is the polynomial corresponding to the parity of the two functions. The polynomial $p \ p$ corresponds to their AND,w hich makes it easy to see that $p \qquad p$ corresponds to their OR Note that the inputs have degree i.e., they are very simple. Since the degree is not increased by computing the sum, the parity gates do not have to be approximated. On the other hand, unbounded fan-in OR gates can greatly increase the degree of the computed functions. We will approximate the OR gates so that the approximated function will have fairly low degree. The following lemma will serve as the basis for the approximation.

Lemma. *Let* $g \quad ,g_m$ *be Boolean functions of degree at most* h *If* $r \quad$ *and* $f \quad \bigvee_i^m g_i$ *then there is a function* f *of degree at most* rh *that differs from* f *on at most* $n^{\ r}$ *inputs.*

Proof. Randomly select r subsets $I_j \subseteq\{ \quad ,m\} \quad j \quad r$ where each i is independently included in I_j with probability Let f_j be the sum of the g_i with $i \quad I_j$,a nd consider $f \quad \prod_j^r f_j$ We claim that the probability that f satisfies the requirements of the lemma is non-zero. It is clear that the degree of the polynomial for f is at most rh Furthermore, consider an input ;w e claim that the probability that $f \quad f$)i s at most ^{r}.T o see this, consider two cases. If $g_i \quad$ 0f or every i then both $f \quad$ and $f \quad$ On the other hand, if there exists an index i for which $g_i \quad$ then f and for each $j \ f_j \quad$ independently with probability at most Therefore, f with probability at most ^{r} and the expected number of inputs on which $f \quad f$ is at most $n^{\ r}$ Hence for at least one particular choice of the sets I_j the polynomial f differs from f on at most $n^{\ r}$ inputs. ∎

To nish the proof, assume that there is a circuit of size s and depth d to compute the k-threshold function for inputs of size n.N ow apply Lemma with $r \quad \lfloor n \quad ^d \rfloor$ to approximate the OR gates in this circuit. The functions computed by the gates at the ith level will be approximated by polynomials of degree at most r^i Therefore, each resulting approximation p_k of the k-threshold function will have degree at most r^d Lemma implies that for $k \quad \lceil n \quad r^d \quad \rceil$ the polynomial p_k differs from the k-threshold function on at least $\binom{n}{k}$ inputs. This shows that $s \ ^{n \ r} \quad \binom{n}{k}$ From this, routine calculations yield

that

$$s \quad \binom{n}{k} \quad r \quad n \quad \frac{r}{\sqrt{\pi n}}$$

which establishes the desired exponential lower bound. ∎

Smolensky generalized this result to prove that every constant-depth circuit that decides whether the sum of the inputs is modulo p using AND OR and modulo-q gates has exponential size, where p and q are powers of di erent primes

How far can one relax the assumption on bounded depth and still obtain superpolynomial lower bounds? The methods of Yao, Hastad and Razborov can be extended to depth near $\log n / \log \log n$ One cannot hope for much more, since the parity function can in fact be computed by a linear-size circuit of depth $O(\log n / \log \log n$

Perhaps the deepest result on circuit complexity is contained in the groundbreaking paper of Razborov 1985a). He gave a superpolynomial lower bound on the monotone circuit complexity of the clique problem, without any restriction on the depth. Shortly afterwards, Andreev used similar techniques to obtain an exponential lower bound on a less natural $\mathcal{NP}$-complete problem. Alon and Boppana by strengthening the combinatorial arguments of Razborov, proved an exponential lower bound on the monotone circuit complexity of the k-clique function.

Theorem. *If C is a monotone circuit with ^{n} input bits that decides whether a given graph on n nodes contains a clique with at least s nodes, then the number of gates in C is at least*

$$- \quad \frac{n}{s \quad \log n} \quad ^{\sqrt{s}}$$

∎

The proof uses a much more elaborate application of the approximation technique. The main combinatorial tool used is the "sunflower theorem" of Erdös and Rado (see Chapter

How different can the monotone and non-monotone circuit complexity of a monotone function be? Pratt proved that the monotone circuit complexity of Boolean matrix multiplication is n This, together with the $O\ n^{\log}$ matrix multiplication technique of Strassen proves that these two notions are distinct. Razborov (1985b), using techniques similar to those used for the clique lower bound, showed that the perfect matching problem, which is in $\mathcal{P}$ has superpolynomial monotone circuit complexity thereby establishing a superpolynomial gap. Tardos showed that this could be increased to an exponential separation, by combining the arguments of Razborov 1985a), Alon and Boppana and results of Grötschel, Lovász and Schrijver on the polynomial computability of a graph function that is closely related to the clique function (see Chapter

As remarked above, no methods are known to handle general circuits with depth greater than $\log n$ In the case of monotone circuits with fan-in however, a version of

the random restriction method has been successfully applied by Karchmer and Wigderson to prove a lower bound on the depth proportional to log n It is clear that a circuit with fan-in and size N must have depth at least log N hence Theorem implies that every monotone circuit with fan-in computing the k-clique function must have depth n However, the function that Karchmer and Wigderson consider is computable by polynomial-size monotone circuit, and so no non-trivial bound on the depth is implied by only considering its size.

Karchmer and Wigderson considered the **undirected reachability problem** given a graph G and two nodes s and t is there an s t path in G This problem is clearly in $\mathcal{P}$ and in fact, it can be decided by a polynomial-size monotone circuit that has depth $O(\log n$ Karchmer and Wigderson proved the following result:

Theorem. *There exists a constant c> such that if C is a monotone circuit with fan-in that solves the undirected reachability problem for a graph on n nodes, its depth is least c* log n

The proof, which uses a version of the random restriction method, is quite involved and is not given here. We describe, however, the starting point, which is a new characterization of the depth of circuits with fan-in at most in terms of communication complexity thereby establishing a surprising link with the material of the previous section.

Consider the following game between two players. The game is given by a Boolean function f in n variables. The rst player gets $x \in \{$ $\}^n$ such that f x and the second player gets $y \in \{$ $\}^n$ such that f y The goal of the game is that the two players should agree on a coordinate i such that x_i y_i Let f denote the minimum number of bits that the two players must communicate to agree on such a coordinate. (For example, the rst player could tell x to the second player, and then the second player can find an appropriate coordinate to tell to the rst player, so f $n+1 \log n$ Karchmer and Wigderson proved that the minimum depth in which a Boolean function f can be computed with a circuit with fan-in is equal to f A similar characterization can be given for the monotone circuit complexity of monotone Boolean functions.

In the case of the undirected reachability problem, the corresponding game can be phrased as follows: the first player is given an $s, t]$-path and the second player is given an $s, t]$-cut, and the goal of the game is to find an edge in the intersection of the path and the cut. Consider the following protocol for this connectivity game: the rst player sends the name of the midpoint on the path, and the second player responds by telling on which side of the cut this node lies. This protocol requires $O(\log n$ rounds, and in each round the first player sends log n bits and the second player sends

Karchmer and Wigderson prove that even if the second player were allowed to send O n)b its in each round instead of just the players would still need at least $\Omega(\log n$ rounds. The claimed lower bound on the monotone circuit depth is a consequence of this fact.

Data structures

Imagine a huge science library It contains a wealth of information, but to make this information useful, catalogues, reference and review volumes, indices (and librarians) are needed. Similarly information in the memory of a computer is useful only if it is accessible, i.e., it is provided with extra structures that make the storage, retrieval, and modification of this information possible, and in fact easy This is particularly important when implementing complicated algorithms: the fast storage and retrieval of certain partial results of the computation is often the main bottleneck in speeding up such algorithms. Such auxiliary structures, called **data structures** are becoming increasingly important as the amount of information stored increases.

The theory of data structures is very broad and we shall restrict ourselves to two examples that illustrate the depth of combinatorial ideas used in this field. For a more thorough treatment, see Aho, Hopcroft and Ullman Tarjan and Gonnet

a. Shortest paths and Fibonacci heaps. Let $G \quad V\ G\ ,E\ G$ be a graph with n nodes and m edges, and with a specified node s Let every edge e have a non-negative length $c\ e$ We want to find a shortest path from s to every other node. We have seen in Chapter that using Dijkstra's algorithm, this is quite easily done in polynomial $O\ n$ steps. (To be precise, we use the RAM machine model of computation, and a step means an arithmetic operation addition, multiplication, comparison, storage or retrieval of numbers whose length is at most a constant multiple of the maximum of $\log n$ and the length of the input parameters.) Let us review this procedure.

We construct a subtree T of G one node at a time. We shall only be concerned with the nodes of this tree,s o we consider T as a set of nodes. Initially,w e let $T \quad \{s\}$ At any given step, for each $v \quad T$ we know the length of the shortest path from s to v i.e., the distance $d\ s, v$ It would be easy to also obtain the edges of the tree; then the unique $s, v]$-path in this tree realizes this distance.

The essence of Dijkstra's algorithm is to find an edge $uv \quad E\ G$ with $u \quad T$ and $v \quad V\ G\ \setminus T$ for which $d\ s, u \quad c\ uv$ is minimal, and then add v to T As shown in Chapter we then have that $d\ s, v \quad d\ s, u \quad c\ uv$ The issue is to find this edge economically At rst glance, we have to select the smallest member from a set of size $O\ m$ and we have to repeat this n times, so this rough implementation of Dijkstra's algorithm takes $O\ mn$ steps.

We can easily do better, however, by keeping track of some of the partial results that we have obtained. Let S denote the set of nodes not in T but adjacent to T.F or each node $v \quad S$,w e maintain the value $v \quad \min\{d\ s, u \quad c\ uv\ \}$ where the minimum is taken over all edges uv with $u \quad T$ For $v \quad S$,w e define v for notational convenience. Clearly v is an upper bound on $d\ s, v$ At the beginning, $v \quad c\ sv$ for each neighbor v of s and u for each other node u A step then consists of (a) selecting the node $v \quad S$ for which v is minimum and setting $d\ s, v \quad v$ (b) deleting v from S and adding it to T c) adding each neighbor w of v that is in $V\ G\ \setminus\ T \quad S)$t o S and (d) updating the value w for each neighbor w of v that is in S by

$$w \quad \min \quad w\ ,d\ s, v \quad c\ vw$$

This way it takes $O\ n$ steps to select the node $v \quad S$ for which v is minimum, and so the total number of steps spent on selecting these nodes is $O\ n$ There is also the time

needed to update the values w this is a constant number of steps per node, and we have at most $d\ v$ nodes to consider, where $d\ v$ is the degree of v Updating therefore takes $O\ \sum_v d\ v$ $O\ m$ steps, which is dominated by $O\ n$ by maintaining the current best path lengths, Dijkstra's algorithm takes $O\ n$)s teps

Can we do better? It is natural to assume that we have to take at least m steps, in order to read the data. If m is proportional to n the algorithm just described is best possible. But for most real-life problems, the graph is sparse, i.e., m is much smaller than n and then there is space for improvement. To obtain this improvement, we shall store the set S together with the values v in a clever way

A first idea is to keep the set S sorted in order of the value of v This makes it trivial to select the next node v and delete it from S but to achieve(c and d we insert new items in the sorted list, which can be done in $O(\log n$ steps per insertion. However, even this is non-trivial. If we simply store the sorted elements of S in an array i.e., in consecutive fields, then to insert a new element, we expect to move half of the old elements for each insertion. Another possibility is to store these elements in a **list** each element is stored along with a **pointer** which specifies the memory location of the next element in the list. In this data structure, insertion is trivial, but to find the point of insertion, we must traverse the list, which takes a linear number of steps. Advantages of both methods can be combined using a data structure called a **binary search tree**.W e shall not discuss these in detail, since we will show how to do better with another kind of data structure, called a heap. Nonetheless, Dijkstra's algorithm with the current best path lengths stored in a binary search tree takes $O\ m \log n$ steps. This may be much better than $O\ n$ but there is still room for improvement.

At this point, it is worth while to formulate the requirements of the desired data structure in an axiomatic way.W e have some objects, the elements of S,w hich are to be stored. Each object has a value v associated with it, which is called its **key** Reviewing the algorithm, we see that we must perform the following operations on this collection of data:

DELETEMIN. We might want to find the element of S with smallest key and delete it from S (steps (a) and (b)).

INSERT. We might want to add new elements to S (step c)).

DECREASEKEY. We might change the key of elements of S in fact, we only need to decrease it (step (d)).

Observe that and are performed $O\ n$ times, since every node is added at most once and deleted once, whereas is performed $O\ m$ times.

As mentioned above, a heap is a data structure that can handle these operations in logarithmic time. Since DECREASEKEY is performed more often than the other two operations, we can improve the overall running time by decreasing the cost of performing just this operation. Fredman and Tarjan showed how to do this by using a more sophisticated data structure, called a Fibonacci heap.

A **heap** is a rooted tree defined on the elements of S with the property that the key of any node is no more than the key of any of its children. In particular, the root is an element with the smallest key If the tree is a single path, then the heap is a sorted list, but it will be worth while to consider more compact trees.

Before deciding about the shape of the heap, let us discuss how to perform the tasks

The heap itself can be realized by maintaining a pointer from each non-root node to its parent. Moreover, the children of each node are ordered in an arbitrary way and each child contains a pointer to the previous child as well as to the next child. Each parent maintains pointers to its first and last child. Each node has ve pointers, some of which may be undefined: parent, first child, last child, previous sibling, next sibling. Changes in the heap are made by manipulating these pointers.

The most common way to implement operations in a heap is as follows. DECREASEKEY is perhaps the easiest. Assume that we decrease the key of an element p .L et $p\ p\quad p_t$ be the path in the tree connecting p to the root. If p is still at most p)t hen we still have a heap; otherwise, we interchange the elements p and p Next we compare the key of p with the key of p ;i f $p\quad p$ we have a heap; otherwise, interchange p and p and so on. After at most t interchanges we end up with a heap. Note that the tree has not changed, only the vertices have been permuted.

INSERT can be reduced to DECREASEKEY: if we want to add a new element w then we can assign to it a temporary key and make it the child of any preexisting element. Trivially this produces a heap. We can then decrease the key of w to the right value, and reorder the elements as before.

Finally DELETEMIN can be performed as follows. Let r be the root element of the heap. Select any leaf p of the tree and replace r by p This interchange deletes the root, but we do not necessarily have a heap, since the key of p may be larger than the key of one or more of its children. Find the child with smallest key and interchange that child with p It is easy to see that the resulting tree again can violate the heap condition only at the node p If p has larger key than some of its children, then find its child with the smallest key and interchange them; and so on. Eventually,w e obtain a heap.

The **height** of a node in a rooted tree is the maximum distance to a leaf; the height of the tree is the height of its root. If the tree has height h then the operations INSERT and DECREASEKEY take $O\ h$ steps; to make these operations efficient, we want the tree as short as possible. But DELETEMIN puts limits on this: it also involves $O\ h$ interchanges, but before each interchange, we must also find the child with smallest key and this takes roughly d steps for a node with d children. If we use **balanced k-ary trees** in which, with at most one exception, all internal nodes have k children and each leaf is at distance h or h from the root, then $h\quad \log_k n$ and so the total number of steps is $O\ n\log_k n\quad m\log_k n\quad nk\log_k n$ The best choice is $k\quad m/n$ and this shows that Dijkstra's algorithm with the current best path lengths stored in a k ary heap takes $O\ m\log n/\log\quad m/n$ steps, which is a slight improvement.

One can use more sophisticated trees with a more sophisticated implementation of the basic operations and with a more sophisticated way to count steps. A rooted tree is called a **Fibonacci tree** if

for every node v and natural number k the number of children of v with degree at most k is at most k

(We use the term degree in the graph-theoretic sense: the degree of a non-root node is one larger than the number of its children.)

The **degree** of the tree is the degree of the root. We want to build heaps on such

trees. For technical reasons, it will be convenient to add an artificial element r with key hence r is always the root. Moreover, for the root we shall impose the following condition, stronger than

The degrees of the children of r are distinct.

A **Fibonacci heap** is a heap whose underlying tree is a Fibonacci tree that satisfies condition We are going to show that by using Fibonacci heaps, we can implement Dijkstra's algorithm to run in $O\ m\quad n\log n$ steps, which is best possible for every m $n\log n$ For very sparse graphs, this is, in some sense, an optimal implementation of Dijkstra's algorithm, but other algorithms may be better.

Note that the subtree of a Fibonacci tree formed by a node and its descendants is also a Fibonacci tree. If we delete a node and its descendants then the only node where condition could be violated is the grandparent of the deleted node. In particular, if we delete a child of the root and its descendants, we are left with a Fibonacci tree. By applying induction to this observation, we obtain the following lemma, which explains the name Fibonacci tree.

Lemma. *Let F and F Then the number of nodes in a Fibonacci tree of degree k is at least F_k the k nd Fibonacci number.* ∎

It follows that a Fibonacci tree with n nodes has degree $O(\log n$ More generally each node has degree $O(\log n$ which follows by considering the Fibonacci tree formed by this node and its descendants.

Assume now that we have a Fibonacci heap, and we want to perform INSERT, DELETEMIN and DECREASEKEY operations. In each case, we will rst produce a heap that satisfies the Fibonacci property at all non-root nodes; we will then give a procedure that restores the stronger property at the root.

(a) INSERT. Add the new node x as a child of r

(b) DELETEMIN. Of course, we do not want to delete the root, but the minimal "real" element. Find the child of the root with the smallest key delete it, and make its children have the root as their new parent.

(c) DECREASEKEY. Suppose that we want to decrease the key of a node v If v is a child of the root, simply decrease the key Otherwise, let $v\ v\quad v_t r$ be the path connecting v to the root. Delete the edge connecting v to its parent v and let v become a child of the root. The resulting tree satisfies the heap condition even with the decreased key Moreover, condition is satisfied by all non-root nodes except possibly by v the grandparent of v .U ntil condition is satisfied at all non-root nodes, fix the violation at v_j by making v_j a child of the root. After at most t steps, we obtain a tree that satisfies for all non-root nodes.

(d) For each of the three operations, we finish by restoring property To do this, we look at the degrees of the root's children, and assume that two children u and v have the same degree t Suppose that the key of u is no more than the key of v;t hen we delete the edge vr and make v a child of u.W e will show that property remains valid at every non-root. This is trivial for all nodes except u To see that it holds for u consider any

s If $s < t$ then u has the same children with degree at most s as before, and so their number is at most s For s t u now has at most s children altogether. (It will be important that a nearly identical argument applies even if a child of v were deleted!(*))

If we nd two children of the root with the same degree then we can transform the heap into one where is still valid at all non-roots, and the root has lower degree. We repeat this until all children of the root have di erent degrees; then is trivially satisfied at the root.

There are two points to clarify

—H ow do we know in(c how many edges $v_i v_i$ must be deleted? To check condition for each v_i would take too much time Instead, we will classify each node as either **safe** or **unsafe** If a node is safe, then deleting one of its children will not violate at a non-root node. In contrast, classifying a node as unsafe implies only that we are not sure if such a violation would occur. Thus, we can always classify the root and its children as safe. In particular, each newly inserted node is safe. We shall reclassify a node in only two cases:

(i) If an unsafe node becomes a child of the root (in a DELETEMIN or DECREASEKEY operation), then it is reclassified as safe.

(ii) If a safe node different from the root loses a child (in a DECREASEKEY operation), then it is reclassified as unsafe.

It follows that in the DECREASEKEY operation, we delete all edges of the path v v $v_t r$ up to the first safe node v_j and make v v_j children of the root. We reclassify v_j as unsafe, and v $, v_j$ as safe. Note that in the parenthetical remark we have already indicated that when r gets a new grandchild v in step (d), it is correct to still classify v as safe.

In performing d), how do we nd those children of the root with the same degree? To sort the degrees would be too time-consuming. We wish to perform (d) in O d steps, where d is the degree of the root after performing steps (a)-(c). For each node we can always store its current degree in an array We will also maintain an array a where a k k $, d$ indicates the name of a child of the root of degree k if one exists. This array is not changed during steps (a)-(c), but is updated during step (d) instead. It is trivial to update a to reflect the deletion of a child of the root. To update a for the new children of the root added during steps (a)-(c), we consider them one at a time. To update a to reflect the next child u,i f u has degree k then we check if a k contains the name of a node. If not, we let a k u If it already contains the name of a child v,t hen we make one of u and v the child of the other, and update a k accordingly This creates a child of degree k which we must then be checked with a k and so forth. Since each collision" of two children with the same degree causes the degree of r to decrease, there are fewer than d collisions overall, and so the new children are added in O d)t ime In fact, if adding t children causes c collisions, the total work of step (d) is proportional to t c

We must still bound the time needed to perform these operations. It is easy to see from Lemma that INSERT and DELETEMIN operations take $O(\log n$ steps. But a DECREASEKEY operation may take enormous time! For example, if the (Fibonacci) tree is a single path from the root, with all nodes but the root and its child unsafe, then it

takes about n steps to decrease the key of the bottom node. Furthermore, if the root has roughly $\log n$ children, then adding just a single child of the root could take roughly $\log n$ steps.

The remedy is a book-keeping trick called **amortization of costs** Imagine that we maintain the Fibonacci heap as a service. The customer may order any of the INSERT, DELETEMIN and DECREASEKEY operations. For each operation, we ought to charge him the actual cost, say a cent for each step. But suppose that we also require that he pay a deposit of one dollar for each unsafe node that is created, and a deposit of cents for each child of the root that is created. If either the number of unsafe nodes or the number of children of the root decreases, the appropriate deposit is refunded. With this billing system, an INSERT or DELETEMIN operation still costs only $O(\log n$ cents, but now we can bound the cost (to him) of a DECREASEKEY operation. Let t be the number of nodes to be made children of the root; this is at most one larger than the number of unsafe nodes becoming safe. Since in step (c), at most one node becomes unsafe, the customer then gets a net refund of at least t cents. The actual cost of step (c) is proportional to t certainly at most t The actual cost of step (d) is proportional to t c certainly at most t c However, in step (d), the customer also gets a refund of c cents. The total cost to the customer of steps (c) and (d) is at most dollars: with this billing system, a DECREASEKEY operation costs only a constant amount.

Summarizing, we have shown the following theorem.

Theorem. *In a Fibonacci heap, performing n INSERT, n DELETEMIN and m DECREASEKEY operations takes $O\ n \log n$ m steps.* ∎

For our original problem we get the following result.

Theorem. *Dijkstra's algorithm can be implemented, using Fibonacci heaps, in $O\ n \log n$ m steps.* ∎

b. Shortest spanning trees and the UNION–FIND problem. Many of the data structures discussed in the previous subsection can also be used in computing a shortest spanning subtree of a graph. In particular, Fibonacci heaps can be used to implement Prim's algorithm to run on a connected graph G with n nodes and m edges in $O\ m$ $n \log n$ time. However, in some cases, we may already know the sorted order of the lengths of the edges, or can find this sorted order extremely quickly such as when the lengths are known to be small integers. In these cases, we can obtain an even more efficient algorithm by using Kruskal's algorithm implemented with a data structure with surprising combinatorial complications. For the following discussion, assume that the sorted order of the edge lengths is known in advance.

Kruskal's algorithm is very simple: it takes the edges one-by-one in the given sorted order, and it adds the next edge to a set T if it does not form a circuit with the edges already in T otherwise, it disposes of the edge. This seems to take m steps, except that we must check whether the new edge forms a circuit with T Let uv be the edge considered.

To search T for a $u, v]$-path would be too time-consuming; it would lead to an $O\ mn$ implementation of Kruskal's algorithm.

We can do better by maintaining the partition $\{V \quad , V_k\}$ of $V\ G$ induced by the connected components of the graph $V\ G\ , T$ Each iteration amounts to checking whether u and v belong to the same class; if not, we add uv to T Furthermore, updating the partition is simple: adding uv to T will cause the two classes containing u and v to merge.

To implement Kruskal's algorithm efficiently,w e must therefore find a good way to store a partition of $V\ G$ so that the following two operations can be performed efficiently:

FIND. Given an element u return the partition class containing u

UNION. Given two partition classes, replace them by their union.

We assume that each partition class has a name, and for our purposes, it will be convenient to use an arbitrary element of the class to name the partition class. We shall call this element the **boss** In a UNION operation, we can keep either one of the old bosses as the new boss. Kruskal's algorithm uses m FIND operations and n UNION operations.

A trivial way to implement a UNION-FIND structure is to maintain a pointer for each element, pointing to the boss of its class. A FIND operation is then trivial; it takes only one step. On the other hand, to do a UNION operation we may have to redirect almost n pointers, which yields an $O\ n$ implementation of Kruskal's algorithm. This is unsatisfactory for sparse graphs, and so we must do the UNION operation more economically

An almost trivial observation already yields a lot: when merging two classes, we redirect the pointers in the smaller class. We call this rule **selection by size.** To estimate the number of steps needed when using this rule, observe that whenever a pointer is redirected, the size of the class containing it gets at least doubled. Hence each pointer is redirected at most $\log n$ times. The total number of steps spent on UNION operations is therefore $O\ n \log n$ and we get an $O\ m \quad n \log n$ implementation of Kruskal's algorithm. For $m \quad n \log n$ this is optimal.

To be able to do better for really sparse graphs (e.g., with a linear number of edges), we use a more sophisticated way to keep track of the boss. We shall maintain a rooted tree on each class, with the boss as its root. Each UNION operations then takes only constant time: we make one boss the child of the other. But this makes the FIND operation more expensive: we have to walk up in the tree to the root, so it may take as much time as the height of the tree. This suggests that we should keep the trees short. We can use an analogue to the selection by size rule, called **selection by height** when merging the two trees, if r is the root of greater height, then it is made the parent of r the root of the other tree. This increases the height only if the two trees had the same height.

Of course, it is time-consuming to compute the height of the trees at each UNION operation, but we can maintain the height $h\ v$ for each node v This is easily updated: it changes only if the union of two trees is performed and the roots have $h\ r \quad h\ r$ then is added at the new root. It is easy to verify by induction that the number of elements in a tree with root r is at least $^{h\ r}$ Hence $h\ r \quad \log n$ for every r and the cost of a FIND operation is $O(\log n$ This does not yet yield any improvement in the implementation of Kruskal's algorithm.

But we can use another idea, called **path compression** Suppose that we perform a FIND operation which involves traversing a fairly long path $v \quad v_k r$ Then we can traverse this path again, and make each v_i the child of the root. This doubles the number of steps, but the tree becomes shorter.

We combine this idea with a variant of selection by height, called **selection by rank.** For each element v,w e maintain a number v called its **rank** The rank of each node is initially if two trees with roots r and r are merged, where $r \quad r$ we make r a child of r and update by setting

$$v \quad \begin{array}{ll} r & \text{if } v \quad r \text{ and } r \quad r \\ v & \text{otherwise.} \end{array}$$

A path compression does not change The number v is no longer the height of v but it will be an upper bound on the height. Moreover, the number of elements in a tree with root v is still at least ^{v} We shall need the following generalization of this fact, which also follows by induction.

Lemma. *The number of elements v with $v \quad t$ is at most $n/ \ ^{t}$* ∎

For each leaf $v \quad v$ is strictly increasing along any path to the root. Note that this guarantees that the height of the tree is at most $\log n$

Tarjan showed that using selection by rank with path compression reduces the cost substantially: the average cost of a FIND operation grows only very,v ery slowly

Let us recall Ackerman's function from Chapter First, we define a series of functions $f_i \quad \mathbb{N} \quad \mathbb{N}$ by the double recurrence

$$f \quad n \quad n, \quad f_i \quad i$$

$$f_i \quad n \quad f_i \ f_i \quad n$$

Thus, $f \quad n \quad ^{n} \quad f \quad n$ is roughly a tower of n 2's, and so on. Ackerman's function is the diagonal $A \ n \quad f_n \ n$ This grows faster than any f_i and in fact, faster than any primitive recursive function. The **inverse Ackerman function** n is defined by

$$n \quad \min\{k \quad A \ k \quad n\}$$

This function grows extremely slowly e.g., slower than $\log \log n$ or $\log \ n$ We shall also need to introduce inverse functions $_i$ of the f_i defined by

$$_i \ n) = \mathrm{m} \ \mathrm{ax}\{k \quad f_i \ k \quad n \quad \}$$

The definition is made so that for fixed $n \quad _i \ n$ is strictly decreasing as a function of i until it reaches Tarjan's result, in a slightly weakened form, is as follows:

Theorem. *In a rooted forest with n elements, using selection by rank and path compression, m FIND operations and at most n UNION operations take $O \ n \ m \quad n$ steps.*

Proof. A UNION operation takes only a constant number of steps. To analyze the FIND operation, we rst develop a few tools. For each non-root node v,l et v denote its parent. We define the **level** of a node v as the least i for which $_i$ v $_i$ v a root is on level (Note that if $_i$ v $_i$ v then $_i$ v $_i$ v Initially,e ach node is therefore on level When a node becomes a non-root, it then reaches a positive level. Note that from this step on, v does not change. The value v can change in only two ways: v may get a new parent from a path compression) or v has the same parent and yet v]c hanges (from a UNION operation). In either case, v increases. Hence the level of the node v can only increase with time. On the other hand, the level of a node remains very small: it is bounded by the least i for which $_i$ n $_i$ which is easily seen to be at most n which is O n

Let v $v_k r$ be a path that is being compressed, where r is a root. The cost of this compression is proportional to k using the charging analogy again, let us say at most k dollars. Consider a node v_j j k on the path, and let i be its level. If $_i$ r $_i$ v_j then charge one dollar to the node. Otherwise, charge one dollar to the customer.

How much do we charge to the customer per path compression? If he is charged for a node v_j at level i,t hen by the monotonicity of $_i$ and ,w e see that $_i$ v_j $_i$ v_j $_i$ r This implies that v_j v_k,r are at level i 1o r lower, i.e., v_j is the last node at level i on the path. So the customer gets charged for at most one node at each level, which is a total charge of O n For m path compressions, this is a total of O $m\alpha$ n

How much charge is left on the nodes? While a node v stays on level i,t he value $_i$ v increases whenever v is charged a dollar, and so the total charge it accumulates is bounded by the maximum value $_i$ v can attain. Note that $_i$ v $_i$ v by the definition of level i and so from the definition of $_i$ we have

$$v \quad f_i \;_i\; v \quad f_i \; f_i \;_i\; v \quad f_i \; f_i \;_i\; v \quad f_i \; v$$

and hence,

$$_i \quad v \quad v$$

So the charge accumulated by a node v while at level i is at most v and since v never decreases, we can use the final value in this bound. Adding this over all nodes, we can use Lemma to show that the total contribution of level i to the charges to the nodes is at most

$$\sum_v \quad v \quad n \quad \sum_t t\frac{n}{t} \quad n.$$

Since there are O n levels, the total charge to the nodes is O $n\alpha$ n ∎

Corollary *Kruskal's algorithm, with pre-sorted edges, can be implemented in* O $m\alpha$ n *steps.* ∎

For a discussion of other implementations of Kruskal's algorithm and its relatives, see Tarjan

Cryptography and pseudorandom numbers

Let $f \quad \{ \quad \} \rightarrow \{ \quad \}$ be a one-to-one function, and assume that this function can be evaluated in polynomial time. Can the inverse function be evaluated in polynomial time? We don't know the answer, but it is quite likely that the answer is in the negative; there are some suspected examples (and some constructions that have been disproved). It turns out that such **one-way functions** and their extensions, could be used in various important applications of complexity theory We examine some of these applications and constructions.

a. Cryptography The basic goal of cryptography is to provide a means for private communication in the presence of adversaries. Until fairly recently cryptography has been more of an art than a science. No guarantees were given for the security level of the codes, and in fact, all the classical codes were eventually broken. Modern cryptography has suggested ways to use complexity theory for designing schemes with provable levels of security We will not be able to discuss in detail, or even mention, most of the results here. We intend rather to give afl avor of the problems considered and the results proved. The interested reader is referred to the surveys by Rivest Goldreich Goldwasser or to the special issue of SIAM Journal on Computing (April, on cryptography

A traditional solution uses secret-key crypto-systems. Suppose that two parties wish to communicate a message M a string of 's and 1's of length n and they agree in advance on a secret key K a string of 0's and 1's of the same length as M They send the encrypted message $C \quad M \quad K$ instead of the real message M where denotes the componentwise addition over GF This scheme is provably secure, in the sense that, assuming the key K is kept secret, an adversary can learn nothing about the message by intercepting it: every string of length n is equally likely to be the message encoded by the string C Unfortunately,i t is very inconvenient to use this system since before each transmission the two parties must *agree* on a new secret key

In the paper that founded the area of modern cryptography Diffie and Hellman suggested the idea of public-key crypto-systems. They proposed that a transmission might be sufficiently secure if the task of decryption is computationally infeasible, rather than impossible in an information theoretic sense. Such a weaker assumption might make it possible to securely communicate without *agreeing* on a new secret key every time, and also to achieve a variety of tasks previously considered impossible.

We illustrate the idea of security through intractability by a simple example. Assume that you have a bank account that can be accessed electronically by a password. If the password is long enough, and you keep it safely then this is secure enough. Except

that the programmer of the computer may inspect the memory learn your password, and then access your account. It would seem that there is no protection against this: the computer has to remember the password, and a good hacker can learn anything stored in the computer.

But the computer does not have to know your password! When you open your account you first generate a Hamiltonian circuit H on, say nodes, and then add edges arbitrarily to obtain a graph G The computer of the bank will only store the graph G while your password is the code of a Hamiltonian circuit H When you punch in your password the computer checks whether it is the code of a Hamiltonian circuit in G,a nd lets you access the account if it is For you, the Hamiltonian circuit functions like a password in the usual sense.

But what about the programmer? He can learn the graph G but to access your account, he should specify a Hamiltonian circuit of G,w hich is a computationally intractable task. This intractability protects your account!

The crucial point here is that given a Hamiltonian circuit, it is easy to construct a graph containing it, but given a graph, it can be quite hard to find a Hamiltonian circuit in it. Unfortunately it is easy to find a Hamiltonian circuit in most graphs, and there is no way known to produce graphs for which finding the Hamiltonian circuit is expected to be difficult.

These considerations motivate the following definition. A **one-way function** is a one-to-one function $f \quad \{ \quad \} \rightarrow \{ \quad \}$ such that f can be computed in polynomial time, but no polynomial-time algorithm can invert f on even a polynomial fraction of the instances of length n Given a one-way function f,w e can choose an $x \in \{ \quad \}$ as our password and store the value $f\ x$ in the computer. The length of the word chosen is the **security parameter** of the scheme. This is indeed done in practice. (The above scheme with Hamiltonian circuits leads to a somewhat weaker notion: a "one-way relation", but for most applications, we need a one-way function.)

The password scheme above is just a simple example of what can be achieved by a **public-key crypto-system** This can have any number of participants. The participants agree on an encryption function a decryption function and a security parameter n Messages to be sent are divided into pieces of length n The system functions as follows:

—E ach participant should randomly choose a public encryption key E and a corresponding secret decryption key D depending on the security parameter n A directory of the public keys is published.

There must be a deterministic polynomial-time algorithm that, given a message M of length n and an encryption key E produces the encrypted message E, M

Similarly there must exist a deterministic polynomial-time algorithm that, given a message M of length n and a decryption key D produces the decrypted message D, M

It is required that for every message $M \quad D, \quad E, M \quad M$

and the crucial security requirement:

One cannot efficiently compute D, M without knowing the secret key D More precisely,f or every constant c and sufficiently large n the probability that a (randomized)

polynomial-time algorithm using the public key E but not the private key D can decrypt a randomly chosen message of length n is less than n^{c}

When a user named Bob wants to send a message M to another user named Alice, he looks up Alice's public-key E_A in this directory and sends her the encrypted message E_A, M By the assumptions, only Alice can decrypt this message using her private key D_A

The question is: how do we find such encryption and decryption functions? The basic ingredient of such a system is a "trapdoor" function. The encryption function E,)f or a xed participant must be easy to compute but hard to invert, i.e., a one-way function; but in order for a one-way function to be useful in the above scheme, we need a further feature: it has to be a **trapdoor function** which is a 2-variable function likeΦ in the scheme above: $\{\ \}^n \times \{\ \}^n \rightarrow \{\ \}^n$ such that for every $E \in \{\ \}^n$ f E,)i s one-to-one and easily computable, but its inverse is difficult to compute, unless one knows the "key" D belonging to E

Given the present state of complexity theory there is little hope to prove that any particular function is one-way or trapdoor (or even that one-way functions exist), or that a public-key crypto-system satisfies the last requirement above. Note that the existence of a one-way function would imply that $\mathcal{P} \quad \mathcal{NP}$ Therefore, a more realistic hope would be to prove the security of a crypto-system based on the assumption that $\mathcal{P} \quad \mathcal{NP}$.H owever, this seems to be quite difficult for two reasons. Complexity theory is mainly concerned with worst-case analysis. For the purpose of cryptography,a verage-case analysis, and a corresponding notion of completeness (such as the one suggested by Levin would be more appropriate. Furthermore, one-way functions lead to languages in $\mathcal{NP}$ which have a unique "witness", whereas the nondeterministic algorithms for $\mathcal{NP}$-complete problems have several accepting paths for most instances.

Over the last ten years, several public-key crypto-systems have been suggested and analyzed. Some have been proven secure, based on assumptions about the computational difficulty of a particular problem (e.g., factoring integers), or on the more general assumption that one-way functions exist.

Rivest, Shamir and Adleman were the first to suggest such a scheme. Their scheme is based on the assumed difficulty of factoring integers. Each user of this scheme has to select a number n that is the product of two random primes. Random primes can be selected using a randomized primality testing algorithm, since every $\log n$)th number is expected to be prime. The public key consists of a pair of integers n, e such that e is relative prime to n where n denotes the number of integers less than n relatively prime to n A message M is encrypted by $C \quad M^e \pmod{n}$ The private key consists of integers n, d where $d \quad e \quad \mod n$ and decryption is done by computing $C^d \quad M \pmod{n}$ Given the prime factorization of n one can nd the required private key d in polynomial time, but the task of nding the appropriate d given only n and e is equivalent to factoring.

Rabin suggested a variation on this scheme in which any algorithm for decryption, rather than any algorithm for nding the decryption key can be used to factor an integer. The idea is to encrypt a message M by $C \quad M \pmod{n}$ (A slight technical problem that has to be overcome before turning this into an encryption scheme is

that squaring modulo a product of two primes is not a one-to-one function, but rather is four-to-one.) An algorithm that can extract square roots modulo n can be used to factor: choose a random integer x and let the algorithm nd a square root y of the integer x mod n with probability the greatest common divisor of x y and n is one of the two primes used to create n

Unfortunately the problem of factoring an integer is not known to be $\mathcal{NP}$-hard; it would be conceptually appealing to suggest schemes that are based on $\mathcal{NP}$-complete problems. Merkle and Hellman and since then several others, have suggested schemes based on the subset sum problem. The public key of such systems is an integer vector a a $,a_n$ A message M,t hat is a0 1v ector of length n is encrypted by the inner product C a M One problem with this scheme is that there does not appear to be a private key that can make the task of decryption easier for the intended receiver. Crypto-systems based on this idea have built some additional trapdoor information into the structure of the vector a and so the decryption problem is based on a restricted variant of the subset sum problem, which is not known to be $\mathcal{NP}$-hard. Furthermore, randomly chosen subset sum problems can be easy to solve. In an innovative paper, Shamir used Lenstra's integer programming algorithm to break the Merkle-Hellman scheme; that is, he gave a polynomial-time decryption algorithm that does not need the secret key Since then, several other subset sum-based schemes have been broken by clever use of the LLL basis reduction algorithm see Chapter

The schemes mentioned so far have encrypted messages of length n for some given security parameter n An apparent problem with this approach is that even if we prove that no polynomial-time algorithm can decrypt the messages, it still might be possible to deduce some relevant information about the message in polynomial time. To formalize what it means to exclude this, Goldwasser and Micali suggested the following framework for a randomized encryption procedure and its security Suppose that there is a function B $\{$ $\}^n \rightarrow\{$ $\}^m$ and a randomized polynomial-time algorithm that, for any image B x produces a value y such that B y B x and y is randomly distributed among all such values; an m-bit message can be encrypted by running this algorithm. Intuitively this encoding is secure if, for any two messages M and M and some pair of codes for them, E and E i.e., B E_i M_i i it is "impossible" to gain any advantage in guessing which message corresponds to each encryption. More precisely the randomized encryption based on B is **secure** if, for each pair M $,M$)a ny randomized polynomial-time algorithm that is used to guess, given M $,M$ and an unknown random ordering of E and E ,w hich value comes from which argument, the probability that the algorithm answers correctly is O n ^{c} for all but an n ^{c} fraction of the encryptions, for every $c>$ Note that if the encryption algorithm is a deterministic polynomial-time algorithm, then it is not secure, since one could simply apply the encryption algorithm to M and M to determine the correspondence.

Goldwasser and Micali proposed a way to achieve this level of security by encrypting messages bit by bit. How does one encode a single bit? A natural solution is to append a number of random bits to the one bit of information, and encrypt the resulting longer string. While this was later shown to be an effective approach, Goldwasser and Micali proposed a different randomized bit-encryption scheme based on a function B $\{$ $\}^n \rightarrow\{$ $\}$

and proved its security based on a number-theoretic assumption, namely on the assumed difficulty of the quadratic residuosity problem.

An integer x is a **quadratic residue** modulo n if $x \quad y \pmod{n}$ for some integer y.T he **quadratic residuosity problem** is to decide for given integers n and x whether x is a quadratic residue modulo n If n is a prime then it is easy to recognize if x is a quadratic residue modulo n e.g., by computing $x^{\ n}$ modulo n this is or if and only if x is a quadratic residue.

The quadratic residuosity problem for composite moduli is more difficult. One has to be careful, however, since there is a polynomially checkable necessary condition that could help in certain cases. To formulate this, define the **Legendre symbol** for any prime n by

$$\frac{x}{n} \qquad \begin{array}{l} \text{if } n \mid x \text{ and} \\ x \text{ is a quadratic residue mod } n \\ \text{if } n \mid x \text{ and} \\ x \text{ is not a quadratic residue mod } n \\ \text{if } n \mid x \end{array}$$

We have seen above that it is easy to compute the Legendre symbol where n is a prime). The **Jacobi symbol** is a generalization of the Legendre symbol to composite n but not in the obvious way: if $n \quad p \quad p_k$ (where the p_i are not necessarily distinct primes), then

$$\frac{x}{n} \quad \prod_{i}^{k} \quad \frac{x}{p_i}$$

It cannot be seen from this definition, but the Jacobi symbol can be computed in polynomial time for any n

Now if n and x are coprime integers then $\frac{x}{n}$ is a necessary condition for x to be a quadratic residue modulo n but it is not su cient: if n is a product of two primes, then exactly half of the residue classes x with $\frac{x}{n}$ are quadratic residues. The Goldwasser-Micali encryption scheme is based on the assumption that there is no efficient way to obtain further information on the quadratic residuosity of x mod n It works as follows: a public key consists of an integer n that is the product of two large primes, and a quadratic non-residue y with $\frac{y}{n}$ The bit is encrypted by a random quadratic residue r (mod n the bit is encrypted by a random quadratic non-residue of the form $r \ y \pmod{n}$ The task of distinguishing encryptions of 0's from encryptions of 1's is exactly the quadratic residuosity problem. Decryption is easy for the intended receiver, who knows the prime factorization of n

Yao has extended this result by proving that a secure randomized bit-encryption scheme exists if a one-way function exists; in fact, from every one-way function one can extract a "secure bit". The following simple construction was given by Goldreich and Levin Let $f \ \{ \ \} \ \rightarrow \{ \ \}$ be a length-preserving one-way function, where a function is **length-preserving** if it maps n-bit strings into n-bit strings, for all n Define a Boolean function by $B \ x \quad f \quad x \quad x$ where, if $n \quad |x|$ then x and x are the first

and last $\lfloor n/ \rfloor$ bits of x and denotes inner product. (If we also want to decode this bit, we take a trapdoor function for f

Diffie and Hellman noticed that under a further assumption, a public-key crypto-system can also be used to solve the **signature problem** where each participant wants a way to electronically sign its messages so that no one else can forge it, in the sense that each recipient can verify that the message must have been signed by the claimed sender. The assumption, which is not very restrictive, is that D, is one-to-one, i.e., E, D, M M for each message M In this case, the system can be used for signatures in the following way When Bob sends a message M to Alice he can use his private decryption key D_B to append the "signature" D_B,M after the message M Given such a signature, Alice can use Bob's public key E_B to convince herself that the message came from Bob, exactly as she received it. The Rivest, Shamir and Adleman scheme has this additional property and therefore can be used for signatures as well.

b. Pseudo-random numbers When random numbers are used in algorithms and crypto-systems, it is essential that the random bits used are unbiased and independent. The speed or the reliability of the algorithm, and the security of the crypto-system depend on the quality of the random numbers used. Natural sources of randomness, such as coins or noise diodes, are fairly slow in generating random bits. On the other hand, for both of these applications, truly random bits could be replaced by any sequence of bits that no polynomial-time algorithm can distinguish from truly random bits. A **pseudo-random number generator** takes a **seed** x a truly random string of length n and expands it to a **pseudo-random string** y of length n^k for some constant k A pseudo-random number generator can be subjected to certain statistical tests. It passes the **next bit test** if after seeing the first i bits of its output y for some $i < n^k$ no polynomial-time algorithm can predict the next bit with probability more than n^{-c} for any constant c

Most computers have built-in pseudo-random number generators; one of the simplest ones is the linear congruential generator (where the seed consists of integers a b m and x and the pseudo-random numbers are generated by the recurrence x_i ax_i $b \pmod m$ This is easily shown to fail the next bit test. Other, more sophisticated pseudo-random number generators can also be shown to output inappropriate sequences, by clever use of the LLL basis reduction algorithm. An example is the binary expansion of algebraic numbers (where the seed is the polynomial defining the algebraic number

The first provably secure pseudo-random bit generator was developed by Blum and Micali They proved that pseudo-random bit generators exist, based on the following paradigm: there exist a polynomial-time computable permutation F of the set $\{\ \}^n$ and a function B $\{\ \}^n \to \{\ \}$,s uch that $B\ x$ yields a secure bit (as discussed above), but given F x $B\ x$ can be computed in polynomial time. Such an F is necessarily a one-way function; B is called the "hard core" of F The Goldreich–Levin construction of a secure bit can be used to show that such a pair of functions exists if a one-way function exists, by taking $F\ x$ $f\ x$ x for some length-preserving one-way function f

The Blum-Micali pseudo-random number generator produces the sequence b $,b_k$ defined by b_i $B\ x_{k\ i}$ and x_i $F\ x_i$ where the random seed is used to select the functions used and the initial vector x The defined pseudo-random number generator can be proved to pass the next bit test. (Informally suppose that we have an algorithm

that can predict b_i B $x_{k\ i}$ given b $,b_i$;w e will use this to contradict the fact that B yields a secure bit. Note that given just $x_{k\ i}$,w e can compute $x_{k\ i}$ $,x_k$ and use these values, F $x_{k\ i}$ $,F$ x_k to compute the bits b $,b_i$ in polynomial time; hence we can use the assumed procedure to predict b_i which is impossible.)

One might wonder whether certain pseudo-random number generators pass statistical tests other than the next bit test. However, Yao proved that if a pseudo-random number generator passes the next bit test then it passes any statistical test, i.e., no randomized polynomial-time algorithm can distinguish the generated pseudo-random numbers from truly random numbers.

c. Zero-knowledge proofs.

Let us return to our example with the bank account access. The programmer of the computer of the bank may be tricky and store your password after you have used it once. Can you avoid using it at all and only *prove* to your bank that you have a password (i.e., know a Hamiltonian circuit in the graph G without giving any help to find it (or mimicking you in any other way)?

This question also comes up in some of the above cryptographic applications: it might be useful to be able to convince someone that a number is the product of two primes, without telling the two primes themselves. This is impossible in the classical sense of proofs, but interactive proof systems, discussed in Chapter make it possible. In fact, this was one of the motivating examples for Goldwasser, Micali and Rackoff when developing their notion of interactive proof systems. Informally,a n interactive proof of a statement is said to be a zero-knowledge proof if the verifier cannot learn anything from the proof except the validity of the statement.

Before formalizing the notion of zero-knowledge proofs, let us describe a solution to the bank problem due essentially to M Blum). To make it more transparent, we imagine another setup: suppose that you are giving a talk on Hamiltonian graphs, and you show your audience a Hamiltonian graph G.F or didactical purposes, you want to convince them that the graph G has a Hamiltonian circuit without showing them the circuit itself. This seemingly impossible task can be accomplished using an overhead projector. You prepare two transparencies: both show the same set V G of nodes, in some random position; the first shows the edges of the Hamiltonian circuit C in G the second, the remaining edges of G On this second transparency the labels of the nodes are also shown, but not on the first! You place both transparencies on the projector and cover them with a piece of paper, then switch on the projector and let the readers choose whether the top sheet or the top two sheets should be removed.

If only the top sheet is removed, the audience sees the graph G politely labelled so that the audience can verify that it is indeed the graph G shown at the beginning. If both upper sheets are removed, the audience sees a Hamiltonian circuit on $|V\ G|$ randomly placed nodes in the plane. In either case, no information is given on how the Hamiltonian circuit lies in the graph G The only information the audience gets is that they see what they expect.)

On the other hand, if you want to cheat and show a graph G that is not Hamiltonian, then either your bottom transparency does not show a Hamiltonian circuit with the right number of nodes,o r the two transparencies together do not show the right graph So there

is a chance of that you get caught! If you repeat this times a bit boring for a talk, but easily done on paper), and you don't get caught then the audience can be reasonably certain that G is Hamiltonian: your chance of getting away with a non-Hamiltonian graph is one in2

To make the above protocol precise, we have to get rid of the physical devices like projectors and transparencies; but this can be done using the methods of cryptography discussed above. The basic cryptographic tool needed for this is a secure bit-encryption scheme. You must be able to encrypt a bit, so that the audience has no chance to figure out on his own what the bit is, but later you can prove which bit was encrypted. To convince the audience that G has a Hamiltonian circuit, you choose a random permutation P,a nd use this permutation to obtain a random isomorphic copy G of the graph G.Y ou encode the permutation, and the n n bits representing the adjacency matrix of the graph G The audience can choose either to ask for a proof that the encoded graph G is isomorphic to the original, or to ask for a proof that G has a Hamiltonian circuit. In the first case, you decrypt every encrypted bit, thereby providing the permutation P and the graph G In the second case, you decrypt only the bits corresponding to edges participating in the Hamiltonian circuit C

There are several ways to formalize the notion of zero-knowledge proofs. The one we shall use is **computational** zero knowledge. We say that an interactive protocol is a **zero-knowledge protocol** if the verifier can generate, in randomized polynomial time, a sequence of communication whose distribution is indistinguishable in polynomial time from the distribution of the true transcript of the conversation.

In our example above, the audience could predict that if it chooses to see both transparencies together, it will see the given graph with nodes randomly drawn in the plane; while if it chooses to see the bottom transparency then it will see a circuit with the right number of unlabelled) nodes, again randomly drawn in the plane.

In contrast, consider the example of the interactive proof for the graph non-isomorphism problem (Chapter Section At rst sight, this seems to be a zero-knowledge protocol, since, so long as the verifier does not deviate from the protocol, he always knows the prover's next move, and hence could generate the conversation himself. There are zero-knowledge protocols for the graph non-isomorphism problem, but this protocol is not, in fact, zero-knowledge, since the verifier can use it to test if a third graph is isomorphic to one of the two in the input (i.e., the verifier can gain extra information by deviating from the protocol). Goldreich, Micali and Wigderson and, subsequently but independently under a somewhat stronger assumption), Brassard and Crepeau proved the following result.

Theorem *If one-way functions exist, then every language in $\mathcal{NP}$ has a zero-knowledge interactive proof.*

Proof. To prove that all languages in $\mathcal{NP}$ have zero-knowledge proofs, one merely has to provide a zero-knowledge proof for a single $\mathcal{NP}$-complete problem. We have sketched such a protocol for the Hamiltonian circuit problem. ∎

Acknowledgments

We would like to thank Shafi Goldwasser and Avi Wigderson for their helpful suggestions and comments on an earlier draft. The research of the second author was supported in part by an NSF Presidential Young Investigator award CCR-89-96272 with matching support from IBM, UPS and Sun and by Air Force Contract AFOSR-86-0078. The research of the third author was supported in part by Air Force Contract AFOSR-86-0078 and by a Packard Research Fellowship. The second and third authors were both supported in part by the National Science Foundation, the Air Force Office of Scientific Research, and the Office of Naval Research, through NSF grant DMS-8920550.
