Correlated Knowledge Gradients for Ranking and Selection of Many Alternatives

Peter Frazier

Presenting joint work with Warren Powell, Savas Dayanik, Diana Negoescu, and Warren Scott

Operations Research & Information Engineering, Cornell University

Thursday February 4, 2010
Department of Applied Mathematics & Statistics
Johns Hopkins University
Outline

1. Ranking and Selection
2. Ranking and Selection with Correlated Priors
3. Theoretical Results
4. Numerical Results
Drug Discovery

- We have a large number \((10^4 – 10^6)\) of chemical compounds.
- We want to find a compound that performs well in a laboratory test.
- We only have time and money to perform a limited number of tests.
  - Typically, the budget allows for between \(10^2\) and \(10^3\) tests.
- Question: which tests should we perform?

Sources: http://www.paa.co.uk/img/labauto/inst_highres/ssi/mini_dispenser.jpg,
Simulation Optimization

- We have a large discrete event simulator with which we can estimate the consequences of a future real-world decision. For example:
  - Designs of a queuing network.
  - Inventory policies for a supply chain.
  - Pricing strategies for a revenue management problem.
  - ...

- We would to find a real-world decision that will work well, according to the simulator.

- Our simulator requires significant time to accurately characterize a decision, and we do not have enough time to do so for each one.

- Question: which real-world decisions should we simulate, and how accurately?
1. Nature fixes $\theta \in \mathbb{R}^k$. $\theta_x$ is the true value of alternative $x$.

2. For $n = 0$ up to $N - 1$, where our sampling horizon is $N$,
   1. Choose $x_{n+1}$ based on $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$.
   2. Observe $y_{n+1} \sim \text{Normal}(\theta_{x_{n+1}}, \lambda_{x_{n+1}})$, where $\lambda \in \mathbb{R}_+^k$ is known.

3. Choose $x^*$ based on $x_1, \ldots, x_N$ and $y_1, \ldots, y_N$.

4. Receive a reward $\theta_{x^*}$.

Goal: Maximize the reward received by finding the best alternative.
Bayesian Ranking & Selection

- We assume that nature has chosen $\theta$ at random from some "population of potential truths" whose distribution is $P_0$.
- We call $P_0$ our prior.
- Let $\pi$ be a policy, which is a method for choosing $x_1, \ldots, x_N$ and $x^*$ based upon the appropriate inputs.
- The expected reward under policy $\pi$ when the truth is $\theta$ is $E^{\pi}[\theta_{x^*} | \theta]$.
- Goal: maximize the expected reward received:

$$\sup_{\pi} \int E^{\pi}[\theta_{x^*} | \theta] P_0(d\theta) = \sup_{\pi} E^{\pi}[\theta_{x^*}]$$
We call $P_n = P_0 \{ \cdot | x_{1:n}, y_{1:n} \}$ our posterior.

Define $\mu^n_x = \mathbb{E}_n [\theta_x]$.

The Bayes-optimal implementation decision is $x^* \in \arg \max_i \mu^N_i$.

Assuming that $x^*$ is chosen in this way, the problem may be written

$$\sup_{\pi} \mathbb{E}_{\pi} [ \max_i \mu^N_i ]$$
A common choice for $P_0$ is an independent normal prior.

Under $P_0$, $\theta_x \sim \text{Normal}(\mu_i^0, (\sigma_i^0)^2)$ and is independent of $\theta_{x'}$.

The independence means that measuring alternative $x$ teaches us nothing about alternative $x'$.

In order to do reasonably well, we need $N \geq k$. 
Outline

1. Ranking and Selection

2. Ranking and Selection with Correlated Priors

3. Theoretical Results

4. Numerical Results
Recall that, traditionally, $\theta_x$ is independent of $\theta_{x'}$ under $P_0$. However, in many situations, we believe that similar alternatives often have similar values. In such situations, our belief on $\theta$ may be more appropriately modeled by a multivariate normal prior.

$$\theta \sim \text{Normal}(\mu^0, \Sigma^0).$$
Suppose the underlying true value of the real-world decision varies smoothly in that decision.

Example: Revenue often varies smoothly with price.

In such situations, two alternatives \( x \) and \( x' \) that are “close” should be more likely under the prior to have similar values \( \theta_x \) and \( \theta_{x'} \).

To accomplish this, we may take the correlation under our prior between \( \theta_x \) and \( \theta_{x'} \) to be larger when \( x \) and \( x' \) are close.
Suppose the alternatives correspond to points in a continuous domain, e.g., prices, or inventory levels.

Let \( \|x - x'\| \) be the distance between alternatives \( x \) and \( x' \) in this domain.

A common choice from spatial statistics is
\[
\text{Cov}_0[\theta_x, \theta_{x'}] = \alpha \exp(-\beta (\|x - x'\|)^p)
\]
for constants \( \alpha, \beta, \) and \( p \).

By varying \( p \) and \( \beta \) we may specify different beliefs about the smoothness of \( x \mapsto \theta_x \).
Several models from medicinal chemistry specify the value of a compound as a linear combination of a set of chemical features $a_1, \ldots, a_J$, plus a compound specific term $b_x$.

The value of compound $x$ is given by

$$\theta_x = a_0 + \sum_{j=1}^{J} c_{xj} a_j + b_x.$$ 

where $c_{xj}$ is some known quantity that tells us how much compound $x$ exhibits feature $j$.

In the Free-Wilson model [Free, Wilson 1964], the features indicate the presence or absence of particular substituents at particular locations, e.g. $c_{xj} = 1$ if compound $x$ has chlorine at location R1, and $c_{xj} = 0$ otherwise.

In the Hansch analysis [Hansch, Fujita 1964], the features are chemical or physical properties, e.g., solubility.
Left: Base benzomorphan molecule, with locations R1-R5 available for substitution.
Right: Set of possible substituents at location R1.

Source: Katz, Osborne, Ionescu 1977
If we take an independent normal prior on the $a_j$ and $b_x$, 

$$a_0 \sim \text{Normal}(\mu_0, \sigma_0^2),$$
$$a_j \sim \text{Normal}(0, \sigma_a^2),$$
$$b_x \sim \text{Normal}(0, \sigma_b^2),$$

then what results is a multivariate normal prior on $\theta$.

Under this prior, two compounds that share similar features will be more likely to have similar values.

We may take a hierarchical prior on the parameters of this model, and then use adaptively updated maximum a posteriori estimates in what follows.
Let $P_0$ be a multivariate normal prior.

Under $P_0$, $\theta \sim \mathcal{N}(\mu^0, \Sigma^0)$, where $\Sigma^0$ is allowed to be non-diagonal.

Define $\mu^n = \mathbb{E}_n[\theta]$, $\Sigma^n = \text{Var}_n[\theta]$.

We have a new prior, but the same goal:

$$\sup_{\pi} \mathbb{E}^\pi \left[ \max_i \mu_i^N \right].$$

We may do well under this prior even if $k \gg N$.

i.e., we can do well even if the number of alternatives is much larger than the number of measurements we can perform.
Correlated Bayesian Ranking & Selection

- With a multivariate normal prior, the posterior is also multivariate normal.

- \( \theta \sim \mathcal{N}(\mu^n, \Sigma^n) \) under the posterior \( P_n \), where \( \mu^n \) and \( \Sigma^n \) may be computed recursively as

\[
\mu^{n+1} = \mu^n + \frac{y_{n+1} - \mu^n_x}{\lambda_x + \Sigma_{xx}^n} \Sigma^n e_x,
\]

\[
\Sigma^{n+1} = \Sigma^n - \frac{\Sigma^n e_x e_x' \Sigma^n}{\lambda_x + \Sigma_{xx}^n}.
\]

where \( x = x_{n+1} \), and \( e_x \) is the vector of all 0s, with a 1 at index \( x \).

- For drug discovery, \( \mu^n \) and \( \Sigma^n \) are defined implicitly in terms of the multivariate normal posterior on \( a_0, a_1, \ldots, a_J \), and \( (b_{x_m})_{m \leq n} \).

- We need not store the belief on those \( b_x \) we have not measured, since our posterior on these is independent \( \mathcal{N}(0, \sigma_b^2) \).
Knowledge-Gradient Policy

The **knowledge-gradient policy** is defined to be the policy that chooses $x_{n+1}$ to maximize the KG factor,

$$KG(x) = \mathbb{E}_n \left[ \max_i \mu_i^{n+1} \mid x_{n+1} = x \right] - \max_i \mu_i^n.$$

- $\mu_i^n$ is the expected value of alternative $i$ given what we know at time $n$.
- $\max_i \mu_i^n$ is the best we can do given what we know at $n$.
- $\max_i \mu_i^{n+1}$ is the best we will be able to do given what we know at $n$ and what we learn from our measurement $x_{n+1}$.
- The KG factor is similar to the expected improvement [Jones et al. 1998], and is the expected value of sampling information [Howard 1998]. When $\Sigma^0$ is diagonal, the KG policy is the (R1, . . . , R1) policy [Gupta & Miescke 1996].

Computing the Knowledge Gradient

Recall that the KG policy chooses the measurement that maximizes the KG factor $\mathbb{E}_n \left[ (\max_x \mu^{n+1}_x) \right] - \max_x \mu^n_x$.

How do we compute this expectation?

We rescale the observation $Z = (y^{n+1} - \mathbb{E}_n[y^{n+1}]) / \sqrt{\text{Var}_n[y^{n+1}]}$, note that $Z$ is standard normal, and compute the expectation as

$$\mathbb{E}_n \left[ (\max_x \mu^{n+1}_x) \right] = \sum_{j=1}^4 \mathbb{E}_n \left[ (a_j + b_j Z) \mathbf{1}_{c_{j-1} \leq Z < c_j} \right].$$
Computing the Knowledge Gradient

In general, to compute the KG factor for a candidate measurement:

- Let $A$ contain those alternatives that are best under the posterior with nonzero probability.
- Let $[j]$ denote the $j^{th}$ entry in $A$.
- Let $a_j = \mu_{[j]}^n$ and $b_j = \sqrt{\text{Var}_n \left[ \mu_{[j]}^{n+1} \right]}$.
- Sort $A$ in order of increasing $b_j$.
- The KG factor is

$$ \sum_{j=1}^{|A|-1} (b_{i+1} - b_i) f \left( \frac{-|a_{i+1} - a_i|}{b_{i+1} - b_i} \right), $$

where $f(z) = \phi(z) + z\Phi(z)$, $\phi$ is the normal pdf and $\Phi$ is the normal cdf.
Global Optimization Example
Global Optimization Example

The graphs illustrate a function with multiple local minima and maxima, indicating the complexity of finding the global optimum. The x-axis represents the independent variable, and the y-axis represents the function value or the log(KG factor), depending on the graph.
Global Optimization Example
Global Optimization Example
Global Optimization Example
Global Optimization Example
Global Optimization Example
Global Optimization Example

The figure shows a graph with two axes: one for the value of the function (y-axis) and another for the log(KG factor) (x-axis). The graph displays multiple curves that oscillate with increasing frequency as x increases. The x-axis values range from 50 to 300, with significant points marked at 50, 100, 150, 200, 250, and 300. The y-axis values range from -14 to 2, indicating the range of the value for the function across different x values.

The curves suggest a complex optimization problem, possibly involving multiple local minima or maxima, which are critical points to consider in optimization algorithms. The plots help visualize the behavior of the function and its logarithmic transformation, which might be useful for understanding the scale and distribution of the data at various points along the x-axis.
Global Optimization Example

![Graph showing global optimization example](image-url)
Global Optimization Example

The figure illustrates the optimization process with three different lines representing different objective functions. The x-axis represents the variable x, and the y-axis represents the value and log(KG factor) for each point. The graphs show the optimization trajectories and the final solution points marked with circles and squares.
Global Optimization Example

Graph depicting the optimization process with various curves and markers indicating the progression of the optimization algorithm. The x-axis represents different `x` values, and the y-axis shows the `value` and `log(KG factor)` on separate scales.
Global Optimization Example

The image shows two graphs. The upper graph plots the value of a function against the variable $x$ on a linear scale. The lower graph plots the logarithm of the KG factor against $x$ on a linear scale. The data points and curves represent the optimization process and the resulting values.
Instead of finitely many alternatives \( \{1, \ldots, k\} \), suppose we have a continuous domain \([0, 1]^d\).

Then \( \theta \) is a function \( \theta : [0, 1]^d \mapsto \mathbb{R} \).

We may take a Gaussian process prior \( \mathbb{P}_0 \) on \( \theta \).

Then \( \mu^n \) is a function \( \mu^n(x) = \mathbb{E}_n[\theta(x)] \).

The KG factor is

\[
\text{KG}(x) = \mathbb{E}_n \left[ \sup_{x' \in [0,1]^d} \mu^{n+1}(x') \mid x_{n+1} = x \right] - \sup_{x' \in [0,1]^d} \mu^n(x').
\]

The KG policy chooses its measurements

\[
x_{n+1} \in \arg\max_x \text{KG}(x).
\]
Recall that the KG factor is
\[
KG(x) = \mathbb{E}_n \left[ \sup_{x' \in [0,1]^d} \mu^{n+1}(x') \mid x_{n+1} = x \right] - \sup_{x' \in [0,1]^d} \mu^n(x').
\]

The KG factor is approximated by
\[
\overline{KG}(x) = \mathbb{E}_n \left[ \max_{x' \in A} \mu^{n+1}(x') \mid x_{n+1} = x \right] - \max_{x' \in A} \mu^n(x'),
\]
where \( A \) is a judiciously chosen set.

As \( A \) gets bigger, the approximation improves.

We may compute the gradient \( \nabla_x \overline{KG}(x) \) and use it in a first order method (e.g., multistart gradient ascent) to approximate
\[
\arg \max_{x \in [0,1]^d} \overline{KG}(x).
\]

This provides an approximation to the continuous KG policy.
Many other derivative-free noise-tolerant global optimization methods exist, e.g.,
- pattern search, e.g., Nelder-Mead
- stochastic approximation, e.g., SPSA [Spall 1992].
- evolutionary algorithms, simulated annealing, tabu search

The KG method is a Bayesian global optimization (BGO) method because it places a Bayesian prior distribution on the underlying but unknown function. (See [Jones et al. 1998]).

The posterior may understood as a surrogate model for the unknown function, and in this way BGO methods are similar to radial basis function methods [Gutmann 2001, Regis & Shoemaker 2007] and response surface methods [Myers & Montgomery 2002].

Surrogate-based methods require more computation to decide where to evaluate next, but often require fewer evaluations to find global extrema.

Our Bayesian R&S problem is a stochastic optimization problem:

$$\sup_\pi \mathbb{E}^{\pi} \left[ \max_i \mu_i^N \right].$$

The optimal solution may be computed using through dynamic programming using Bellman's recursion: $V_N(\mathbb{P}_N) = \max_i \mu_i^N$, $V_n(\mathbb{P}_n) = \max_{x_n} \mathbb{E}_n [V_{n+1}(\mathbb{P}_{n+1})]$.

...but the space of possible posteriors is so large that computation is impossible except for the smallest problems.
Remark

The knowledge-gradient policy is optimal when \( N = 1 \).

This follows by the construction of the KG policy.
Optimality Results

**Theorem**

\[ \lim_{N \to \infty} \arg \max_i \mu_i^N = \arg \max_i \theta_i \text{ almost surely.} \]

This states that the global optimum is eventually discovered. The proof uses a martingale convergence argument to show that every alternative is sampled infinitely often.

**Corollary**

\[ \lim_{N \to \infty} V^0(S^0; N) - V^{KG,0}(S^0; N) = 0. \]

This may be understood as a weak form of asymptotic optimality, although many policies that perform poorly also possess this property, e.g., equal allocation.
Suppose that \( \Sigma^0 \) is diagonal. Then:

1. If there are exactly 2 alternatives (\( k=2 \)), the knowledge-gradient policy is optimal. In this case, the optimal policy reduces to

   \[ x_{n+1} = \arg \max_x \Sigma^n_{xx}. \]

2. If there is no measurement noise, and alternatives may be reordered so that

   \[ \mu_1^0 \geq \mu_2^0 \geq \ldots \geq \mu_M^0 \]
   \[ \Sigma_{11}^0 \geq \Sigma_{22}^0 \geq \ldots \geq \Sigma_{MM}^0, \]

   then the knowledge-gradient policy is optimal.

Global Optimization: Numerical Results

- Six-hump camelback
- Tilted Branin
- Hartman-3
Figure 4.13: CKG with Free Wilson model for 99 compounds using the informative prior and a single truth compounds almost at random just so that it learns something about their values, which renders it a not too different policy from Pure Exploration.

Nonetheless, even with the numerical issues coming up in the noninformative phase, the CKG policy is still doing quite well compared to the other policies, as it is still the only policy that finds the best compounds in the first 100 measurements.

Informative prior
We have also tested the informative prior for this data set of 99 compounds under the Free Wilson model, and the resulting plot can be seen in Figure 4.13. Just as we observed using the 36 compounds data set, the learning rate is again significantly faster than under the non-informative prior.

Average over 100 sample paths on randomly selected subsets of benzomorphan compounds of size 99.
One sample path on the full set of 87,120 benzomorphan compounds.
Correlated beliefs allow us to perform well even with large numbers of alternatives.

The knowledge-gradient policy:
- is “easy” to compute (compared to the optimal policy),
- performs well in numerical experiments,
- and is provably optimal in certain special cases.
